NOTES OF AN EPIDEMIC OF ACUTE ANTERIOR POLIOMYELITIS.

Read in the Section on Neurology and Medical Jurisprudence at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY C. S. CAVERLY, A.B., M.D.

PRESIDENT OF THE STATE BOARD OF HEALTH,
RUTLAND, VT.

The following "Notes" are the result of an investigation undertaken by me in an official capacity at the time of the outbreak, and since continued through private and professional intercourse.

The epidemic was one of an acute nervous disease whose chief distinguishing characteristic was motor paralysis, more or less complete, of one or more members or groups of muscles, and which prevailed in the State of Vermont, chiefly in a single valley, during the summer of 1894. The results of my investigations as far as completed at the time were published in the *Yale Medical Journal* for Nov., 1894, and in the *New York Medical Record* for Dec. 1, 1894. At the time of making these reports it did not seem possible to speak of the epidemic more definitely than as one of "acute nervous disease of unusual type." A further careful study of the complex features of the epidemic, however, and of the subsequent history of many of the cases, together with the corroborative opinions of many able medical men, seems to clear up any doubt that at the time existed as to the correct diagnosis of the essential disease that prevailed.

I may state at once that I am indebted to Professors A. Jacobi, M. Allen Starr and Chas. L. Dana for very valuable aid in arriving at a diagnosis in this series of cases, as well as for notes of the latest pathologic views of poliomyelitis and a literary résumé of that disease. I am also indebted to my fellow practitioners of Vermont who have kindly placed at my disposal the results of their clinical observations of the epidemic. This paper is necessarily largely a recapitulation of the facts heretofore published about this epidemic, with a careful revision of the statistics of the outbreak made from recent observations.

The epidemic, as I have indicated, invaded our valley in the early summer of 1894. It prevailed with increasing severity during July, apparently reached its climax about the first of August, and steadily declined until about the first of October, the last case occurring early in that month.

The early summer was popularly considered unusually hot and dry, though the official figures do not substantially endorse the former opinion. That it was an exceptionally dry season is manifest from the figures of the United States Weather Bureau of the State, which show that the rainfall during the five months from April to August inclusive for this year was one-third less than the average for these months since the opening of the station in the State. The temperature

and humidity statistics show little variation from the average. The territory mainly covered by this outbreak is a portion of the Otter Creek Valley, about thirty miles long and from twelve to fifteen wide, including the sides of the bounding mountains. On the east of this part of the valley is the main Green Mountain range, and on the west the Taconic range, which is a northern extension of the Berkshire Mountains of Massachusetts. Otter creek, the largest stream of water in the State, has its source in the mountains to the south of the affected area, and sluggishly flows in a northerly direction through it, emptying some miles below into Lake Champlain. That part of its course through the affected district is the most populous and likewise the narrowest part of the valley. The city of Rutland is the commercial and geographical center of this area. The towns affected have a combined population of 26,000, of which fully two-thirds dwell in the quarrying and manufacturing centers of Rutland, West Rutland and Proctor.

The starting point of the epidemic, and most of the earlier cases, were at Rutland. In this city occurred 55 of the 132 cases of which I have notes; 27 of the remainder occurred in the town of Proctor, one-sixth the population of Rutland. This town suffered the worst of any in the valley. The remaining fifty cases were scattered over the rural districts in fourteen towns. The most of these cases occurred at considerable elevation above the creek, and many well up on the Green Mountains. Four of these towns with eight of the cases are not in the Otter Creek Valley. The natural drainage of the valley is the creek, and this stream, below Rutland, carries a large amount of sewage. If the disease had shown any preference for those houses immediately on the stream below Rutland, it might at once be inferred that the low water in a sewerage-contaminated stream had some bearing on the etiology of the disease. But such did not appear to have been the case, except, possibly, in the town of Proctor, which is six miles below Rutland and is built on the abrupt bluffs above the stream. Drainage defect in general did not seem to influence the distribution of the disease. The water supply was excluded as an etiologic factor, it being largely from wells in the rural communities, and in the villages from mountain streams and springs. That the general sanitary surroundings and methods of living were in anywise responsible for the outbreak is also more than doubtful, since the disease showed no partiality to that class of the population whose habits and surroundings are the most unsanitary. The so-called laboring classes were oftenest affected, but not out of proportion to their numbers. These classes here, whether among the farming population or in the mills and quarries, have usually pure air, food and water. Hence, general sanitary conditions did not seem to have any influence on the epidemic.

The geologic formation of the valley is not peculiar.

iar. The prevailing formation is limestone, and in the range that skirts the western border of the valley is found the chief marble deposit of Vermont. The valley as a whole is an old lake basin and is pronounced by Prof. G. W. Perry, the State Geologist, as a very ordinary valley.

The outbreak of which I speak consisted of upward of 130 cases of disease in which the commonest clinical manifestation was some degree of motor paralysis of widely varying extent. It will not surprise any one that so large a number of cases presenting a bewildering variety of initiatory constitutional symptoms, as well as local paralyses, should have proved a very knotty problem for the diagnostician. It was long a question whether this was an epidemic of one, two, or more diseases, and along the established lines of symptomatology and pathology there was no solution of the problem. I have been able to collect histories more or less complete of 132 cases directly affected in this epidemic, and this number probably represents at least 90 per cent. of the whole number.

Case 1.—Boy, 3 years, American. Hygienic surroundings good; previous health good; active child; stronger than his brother two years older. No apparent cause. Fell sick June 20. Moderate fever, coated tongue, loss of appetite, sluggish bowels. His condition was confidently ascribed to indigestion, and after two or three days the continuance of the symptoms, though in decreasing severity, proved troublesome of explanation. On the third day his parents insisted that he could not use his legs. It was soon evident that this was the case. His reflexes were normal, sphincters unaffected, no anesthesia or noticeable hyperesthesia. The weakness was most marked in the large extensors of the thigh. After the entire subsidence of his febrile symptoms, his muscular weakness began to improve, at first very slowly. In three weeks he had gone on to full recovery.

This case is an excellent illustration of the mildest type of the disease, a type that included about forty cases.

Case 2.—Boy, 3½ years, Irish. Hygienic surroundings fair; sturdy child; most active of a family of three children. Only apparent cause playing too hard on a hot day. Taken with high fever, temperature 102° to 104° F., nausea, general restlessness and headache. Had incontinence of urine, no albuminuria. On third day acute symptoms subsided except the incontinence of urine. It was then noticed that he had lost the use of his legs. Patellar reflexes diminished and considerable hyperesthesia of the legs. There was also diminution of faradic irritability. The left leg improved rapidly, the right slowly. After six weeks was able to stand and take a few steps by taking hold of chairs. After three months the paralysis and wasting were confined to the right glutei and lower spinal muscles. His efforts to walk have brought on a slight spinal curvature. The incontinence of urine continued in this child until Feb. 1, 1895, when it was relieved by circumcision. The paralysis, however, persists in the glutei and lower spinal muscles and promises to be permanent.

This case illustrates a very common phase of this epidemic, and in most of these cases there is probably some permanent impairment of certain muscles.

Case 88.—Practice of Dr. Gale, Rutland. Girl, 6 years, American. Previous health had been frail. Had had a spinal curvature since she began to walk. Taken suddenly with high fever, nausea, head- and backache. On the fourth day of the attack she was paralyzed in all the extremities and one side of the face. Febrile symptoms subsided at this time. There was extreme hyperesthesia of the whole body and obstinate constipation from seeming lack of power in the abdominal muscles. Facial paralysis speedily passed off. Hyperesthesia and pains in the joints required the use of morphin for several weeks. After nine months she is still paralyzed in all the extremities, being able to flex the fingers and toes slightly and raise the head. The hyperesthesia has passed off.

Case 116.—Practice of Dr. Swift, Pittsford. Boy, 4 years, Italian. Taken with headache, drowsiness and slow hobbling

pulse. Little fever. After four days developed strabismus. Improved speedily and at the end of four days was apparently well. Three days later, after playing too hard, had a return of the original symptoms. Headache, drowsiness, no fever, pulse 45. In two days from this time had a convulsion and speedily died.

Case 32.—Practice of Dr. Marshall, Wallingford. Woman, 21 years. Married and one child of 16 months. Apparent cause fatigue from nursing sick child. First had head- and backache. Pulse 80, temperature 98.6°. On third day pulse 100, temperature 103.5°. Some opisthotonos; bowels regular; urine, 2 pints in twenty-four hours. No albumin, no sugar. Urticarial blotches on the body. During the next three or four days temperature ranged from 100.5° to 102°, pulse about 100. Was unable to speak or swallow. Answered questions by moving the head; in no pain. Sixth day temperature 98.6°; pulse 60. Remained in this condition five days. On the eleventh day complained of severe pain in the stomach, and neck became rigid; pulse 100, temperature 98.6°. During the next two days pulse became very irregular. Complained of severe pain in the right side of the head and right eye. Died at the end of the second week.

Case 4.—Practice of Dr. Fox, Rutland. Boy, 6 years, previous health fair. On two or three occasions had convulsions, presumably due to gastro-intestinal disturbance. Was seized with convulsions while playing on the street; they continued for nine hours. Moderate fever, rapid pulse, vomiting and rigidity of muscles of the neck and back. No paralysis noted during conscious intervals. Retention of urine during the last three days of illness. Death on the sixth day.

These four cases represent various types of the severe form of the disease, and among these cases there were eighteen deaths.

There were a great many cases exhibiting rare and interesting phenomena, a detailed report of which would consume too much time. One of these, during an attack of broncho-pneumonia, had loss of speech for two weeks, and paralysis of one arm which recovered in five weeks. One developed paralysis of both legs in connection with pneumonia. The paralysis in one case was confined to the external rectus of one eye. Several, after apparently recovering from the acute symptoms, were again attacked more severely than at first. Two cases, in which the legs were paralyzed, had a concurrent fever with the characteristic typhoid curve. One case was that of a boy of 6 years who had been at the seashore during the summer, and returning to the town of Proctor after the epidemic was apparently on the wane, on Sept. 5, was attacked with the typical symptoms of poliomyelitis on Sept. 30, and is left with impairment of the extensors of one thigh and the glutei. This case is interesting as showing possibly the length of the incubation period of the poison if we class the disease among the infectious disorders.

Without detailing further individual cases, a condensation of my notes presents the following clinical picture of the epidemic:

Age and Sex.—Ninety cases were under 6 years of age; 39 were boys and 22 girls; sex of the remainder not stated. Fifteen cases were between the ages of 6 and 14; 5 were males and 6 females; sex not stated in 4 cases. Fifteen cases were over 14 years; 9 were males and 6 females. In one series of cases, 7 in number, the age is stated as between "a few months and 9 years," and the sex of none is given. In another of 5 cases, neither age nor sex is stated. It is interesting to note in this connection that there were 9 cases in adults upward of 21 years of age. One of these was a man of 70 who had the familiar symptoms of the milder type of these cases with paralysis of both legs, which passed off in ten days. The other 8 cases were in persons from 21 to 38 years of age. These figures as to age and sex do not differ

from those usually given for poliomyelitis. While it is chiefly a disease of childhood it is not exclusively so. Males are vastly more liable to it.

Nationality.—In those cases in which the nationality is stated 41 were American, 17 Irish, 6 French, and one each was Hebrew, Italian and Swede. I know of no significance to attach to these figures.

Previous Health.—Of the 46 cases in which the previous health of the sufferers is given, in 35 it is given as good, and in 11 as poor. It is quite certain that the strong, healthy children preponderated.

Immediate Cause.—The immediate apparent cause is stated in 37 instances. Of these overheating is mentioned 24 times, chilling of the body 4 times, trauma 4 times, while fatigue, typhoid fever, pneumonia and whooping cough are mentioned. There was a general absence of infectious disease as an etiologic factor in this epidemic. The element of contagium does not enter into the etiology either. I find but a single instance in which more than one member of a family had the disease, and as it usually occurred in families of more than one child, and as no efforts were made at isolation, it is very certain that it was non-contagious.

Initial Symptoms—Fever.—In most of the cases there was a perceptible rise in temperature at the start, though a few are said to have had none. Of the 56 cases in which the temperature is noted, 27 had a temperature at some time of 103°, or more, while in 26 it ranged from 99° to 103°. Three are said to have had "no fever." The duration of the initial fever, where given, varied from a few hours to two weeks. The four cases, however, that are said to have had a fever for more than a week, probably suffered from some complication or some intercurrent disease. Twenty-six cases had a febrile stage lasting from four to seven days, 7 lasting from three to four days, 6 lasting two to three days, 2 lasting one to two days, and four for one day or less.

Digestive Organs.—Nausea was a very common symptom and is mentioned as occurring twenty-six times. It was often the first symptom noted and was probably one of the commonest. Gastralgia occurred in few cases. Thirteen cases were said to have had obstinate constipation, and six had a diarrhea.

Urinary Organs.—Two cases had incontinence of urine and in ten cases there was retention. In no case is albuminuria mentioned.

Skin.—Thirty cases are said to have had a simple erythema, and two had urticaria. There was an entire absence of herpetic and purpuric eruptions.

Nervous System.—Convulsions occurred in 12 cases, all under 14 years of age. Muscular rigidity of the neck or back muscles or both is said to have occurred in 20 cases, of which 5 were fatal. It is a very significant fact that 36 cases are noted as having hyperesthesia of the skin. Only one is said to have had any anesthesia of the paralyzed member. In several instances soreness of the joints of the affected limb was a very painful symptom. Nine cases are said to have suffered from headache alone, 2 from pain in the back and 23 from both head- and back-ache. These symptoms were probably commoner than the figures indicate. There was no general tendency to impairment of the special senses. Two cases are said to have had double vision, 3 strabismus, one was blind and one deaf.

Initial Paralysis.—The paralysis which was the leading and most common characteristic of this series

of cases, occurred in 119 instances. Of the remaining 13, 7 died before paralysis had time to develop, or it could not be determined whether there was really paralysis or not, and the remaining 6 that had no paralysis, all had a group of symptoms very common in the initial stage in those which were paralyzed, such as headache, fever, convulsions or nausea, one or all. In those cases in which the exact day of the paralysis is noted, it is stated to have occurred four times on the first day, eight times on the second, ten times on the third, five times on the fourth, three times on the fifth, once on the sixth, four times on the seventh, and once on the tenth day of illness. It is quite likely that the actual duration of the premonitory symptoms prior to the appearance of the paralysis was often overestimated, since loss of power in the extremities, especially in children, might easily go unnoticed for some time, unless the physician or friends were looking for it. In several instances the loss of power in the legs was the first symptom noticed. The initial paralysis was located as follows:

Both legs	69 cases.
Arm and leg, same side	10 "
One arm	5 "
One leg	7 "
Both legs and one arm	4 "
Tongue and throat	2 "
Both arms	3 "
All the extremities	4 "
Extensors of one thigh	2 "
"Variouly in the arms and legs"	8 "
External rectus of one eye	1 "
One side of the face	1 "
One arm and the opposite leg	1 "
All the extremities and abdominal muscles	2 "
Stated to have had no paralysis	6 "
Not determined	7 "

Of the six cases that are said to have had "no paralysis" all had distinct nervous symptoms explainable only on the supposition that they belonged to this epidemic. All the seven cases in which it was not certain whether they were paralyzed, died early, often with convulsions, and their occurrence at this time seems to warrant their being included in this series.

Of those cases that are known to have fully recovered according to the latest information I can obtain—

Both legs were paralyzed in	43 cases.
Arm and leg, on same side, in	4 "
One arm in	1 "
One arm and both legs in	1 "
External rectus of one eye in	1 "
One leg in	1 "
There was no paralysis in	5 "

That there have been more complete recoveries than this, viz., 56, is quite certain, but I have not been able to trace them.

Fatal Cases.—Eighteen deaths occurred as follows: 1. Boy, 10 years; died within twenty-four hours with convulsions. 2. Boy, 6 years; died on sixth day with convulsions. 3. Boy, 10 months; died on sixth day, paralyzed in both legs. 4. Boy, 4 months; died on sixth day, all the extremities paralyzed. 5. Girl, 11 years; died on third day, no paralysis noted. 6. Girl, 1½ years; died on sixth day, no paralysis noted. 7. Female, 21 years, died on thirteenth day, no fixed paralysis. 8. Male, 19 years; died on fifth day, both legs paralyzed. 9. Sex and age not stated; died with convulsions. 10. Male, 21 years; died on third day, all extremities paralyzed. 11. Sex and age not stated; had paraplegia. 12. Sex and age not stated; had hemiplegia. 13. Girl, 7 years; died on seventh day, all

extremities paralyzed. 14. Boy, under 1 year; no paralysis noted. 15. Boy, 4 years; died on second day of relapse, no paralysis of the extremities, but strabismus. 16. Male, 22 years; died on third day, both legs paralyzed. 17. Male, 38 years; died on sixth day, both legs paralyzed. 18. Girl, 1½ years; died on fourth day.

It will be seen that 10 deaths were among males and 5 among females, and that the sex is not stated in three cases. Seven of those that died are known to have been under 6 years, three between 6 and 14 years, while one died at 19 years, two at 21 years, one at 22 years, and one at 38 years. The percentage of deaths among adults is seen to have been very high.

A further analysis of the deaths shows that five of the cases were paralyzed in the legs, three in all the extremities, and one was hemiplegic. I might state that in the great majority of fatal cases the diagnosis was meningitis. Such a diagnosis was usually not at all inconsistent with the clinical features of the disease. Deducting from the whole number of cases, those which are known to have terminated fatally, and in recovery (74 in all), there remain 58 cases to be accounted for. Just how many of these are still and probably permanently paralyzed, I am not able to state. It was a common experience for a part of the initial paralysis to clear up within the first month, leaving a single member or a single group of muscles weak and wasted. Thus, many cases that at first seemed to be paralyzed in both legs soon improved as to one, and the permanent lesion was seen to be in the other limb or in a few of its muscles. The extensor muscles of the thigh, the glutei, ileo-psoas, calf muscles, and anterior tibial group, in the lower extremity, and the deltoid and extensors of the forearm, were frequent sufferers.

Permanent Paralysis.—Of the 58 cases which my report left unaccounted for, I have been able to get reports of 30 which are still maimed, from six to nine months after the initial attack. Of these 16 are stated to be males, and 12 females. Eighteen are under 6 years, 7 are between 6 and 14 years, and 5 are over 14 years of age. Here again we see the high percentage among the older patients. Of these 30 cases—

All the extremities are paralyzed in	1 case.
Both arms in	1 "
Extensors of one thigh in	6 "
Glutei and lower spinal muscles in	1 "
Both legs in	6 "
Extensors of one thigh and one leg in	2 "
One leg in	6 "
Glutei alone of one side in	1 "
One foot and ankle in	1 "
Extensors of one hand in	1 "
Both legs, thighs and hips in	1 "
One arm in	2 "
Complete hemiplegia in	1 "

The muscular atrophy in most of these cases is marked though combatted by the usual treatment of rubbing, massage and electricity.

During this epidemic and in the same geographical area, an acute nervous disease, paralytic in its nature, affected domestic animals. Horses, dogs and fowls died with these symptoms.

The only reliable facts which I am able to give of the pathologic conditions in these cases among the lower animals are from examinations of the cord of a horse that died paralyzed in the hind legs, and from that of the cord and brain of a fowl which was paralyzed in its legs and wings. Dr. W. W. Town-

send, of Rutland, who made the examination of the horse, says that the examination of a section of the lumbar portion of the cord showed a "granular degeneration and pigmentation of the ganglion cells of the anterior cornua, and atrophy of the anterior nerve roots." He further states that there was no meningitis in this case. Dr. Charles L. Dana, who made the examination of the fowl, with the aid of Dr. Dunham, of the Carnegie Laboratory, found "an acute poliomyelitis of the lumbar portion of the cord and no meningitis." A bacteriologic examination of the same cord by Dr. Dunham gave negative results, and it was found that the inoculating needle did not strike the diseased parts.

It was not infrequently remarked by physicians practicing in this valley at the time of this epidemic, that the usual diseases of children were accompanied with exaggerated nervous symptoms. Headache, convulsions and delirium were common.

It is recorded by Medin, in an epidemic of poliomyelitis which he reports, and to which I shall presently refer, that polineuritis prevailed with poliomyelitis. The pain, hyperesthesia, and tenderness of the extremities suggest such an explanation in some of our cases. Gowers is also cited by Putnam (*American Journal of the Medical Sciences*, March, 1895), as speaking of the combined occurrence of poliomyelitis and neuritis. It will be readily seen that it would be quite impossible to reconcile the widely varying phenomena of this epidemic with the established characteristics of any one disease. So it is not strange that local observers differed in their diagnoses. In collecting notes of this epidemic I did not seek any disease by name, endeavoring only to secure histories of such cases as had had well-marked symptoms of acute nervous disease, the paralysis usually being the test symptom. Meningitis, poliomyelitis and neuritis were mentioned with varying frequency, and it is only a careful study of the epidemic as a whole, giving due weight to the predominating symptoms, the paralysis, of course, being the most striking, together with a knowledge of the latest pathology of these diseases, that seems to warrant the conclusion that the essential disease was poliomyelitis. Some of the commonest symptoms seen in our epidemic were entirely foreign to this disease as long described. Likewise, too, its epidemic character and the simultaneous affection of the lower animals. I am especially indebted to Dr. M. Allen Starr for notes of the latest views of the pathology of poliomyelitis.

In *Zeitschrift für Klin. Med.*, 1892, Goldschneider's views, founded on such cases as ended in autopsies, are given as follows: "The disease begins with a very intense congestion of the central arteries of the spinal cord which come up on each side of the central canal and spread out in the gray matter of the posterior horns, but the posterior horns are chiefly supplied with blood from the peripheral arteries, and hence, are less affected when the inflammation is limited to the distribution of these central arteries. After the engorgement of all the arterial twigs, diapedesis occurs and the surrounding nervous tissue is permeated by small cells and by serum. It is this choking of the gray matter by the inflammatory products which leads to the suspension of functional activity, and when, as in many cases, from impoverished nutrition the cells of the anterior horns are actually disintegrated by the inflammatory products,

permanent destruction of the nerve tissue ensues. Goldschneider believes, therefore, that the primary condition is a congestion in the domain of a definite set of arteries, quite comparable to the condition occurring in the lung in pneumonia and in the intestine in typhoid fever.

Siemerling, in an article on the "Pathology of Infantile Paralysis" in *Archiv für Psychiatrie*, January, 1894, says: "After a careful review of all the literature we reach, therefore, the following conclusion, that in the pathogenesis of infantile paralysis the inflammatory lesion of the interstitial tissue in connection with a distension of the blood-vessels, especially in the region of the anterior spinal arteries, plays the chief rôle. A primary inflammation of the ganglion cells in the sense given by Charcot is not to be admitted."

In view of this newer pathology, showing as it does that the initial lesion is not confined to the anterior horns, but that there is a simultaneous invasion of other portions of the cord, the exceptional symptoms seen in our epidemic are rendered explainable.

The results of autopsies made by Rissler were even more striking. He found an acute parenchymatous inflammation of the anterior horns in the cord with degeneration of the ganglion cells and secondary degeneration of the nerve fibers in the association tracts, in the anterior columns and in the anterior nerve roots; also in the nuclei of the hypoglossus, vagus, facial and abducens nerves. In most of the cases the anterior horns were particularly affected; in other cases, also the peripheral nerves and brain cortex. It was possible that all the nerve nuclei in the medulla and pons should be affected. In the light of these recent pathologic researches taken in connection with the most noted clinical features of this outbreak, viz., the season of the year, the preponderance of cases among children, the widely varying and almost universal paralysis and the low mortality, the conclusion seems unavoidable that the essential disease was poliomyelitis. Under this classification the epidemic at once assumes great importance in several particulars:

1. From the simple fact that it was an epidemic of poliomyelitis.
2. From the great number of cases occurring.
3. From the simultaneous affectation of the lower animals.

While epidemics of poliomyelitis are not unknown or unrecorded, recent authorities speak only vaguely of their occurrence. It has not thus far found a definite place in the descriptions of this disease. The fact that poliomyelitis may occur epidemically, suggests, of course, an infectious origin, a view of the nature of the disease which has only been recently discussed.

I have been able to find the following reference to outbreaks of poliomyelitis of epidemic character, largely through the assistance of Prof. Jacobi.

In the transactions of the Tenth International Congress (Berlin, 1891), Vol. II, Prof. O. Medin reports that Bergenholz in Sweden observed and reported thirteen cases occurring near Lyons, France, four of which were fatal. Medin also cites Eichhorst, who speaks of observations sometimes made of several cases occurring in the same neighborhood. G. Lotmer (*American Journal of the Medical Sciences*, 1843) was told by the parents of a child treated by him for poliomyelitis (teething paralysis), that in a

place where they previously lived eight or ten cases had been known within three or four months. Medin's epidemic, however, is the most extensive of any of which I find a record, and bears in many respects a close resemblance to the Vermont epidemic. The disease appeared in Stockholm in the month of May, 1887, and by Aug. 9 had assumed an epidemic character. Medin saw twenty-nine cases between the latter date and Sept. 23, and knew of forty-four during the summer from May to November. Three of his cases were fatal in the acute stage. "There were noticed paralysis of the abducens in five cases, disturbance of speech in a few; in one case paralysis of the tongue, in several of the accessorius; in others, symptoms referable to the vagus. Disturbance of the voice and paralysis of the muscles of mastication and vasomotor paralysis were seen in two fatal cases. In one ophthalmoplegia externa. At the time of the Stockholm epidemic during August and September, polineuritis appeared and was thought to be due to the same cause. This neuritis was followed by considerable tenderness. These neuritis cases, however, showed no wasting."

It will thus be seen that Medin's observations are very similar to those here recorded, and together with the latest pathologic views of the disease, will seem to mark the neuritis of which he speaks as a varying manifestation of poliomyelitis.

Putnam (*Boston Medical and Surgical Journal*, Vol. CXXIX, p. 509) speaks of the unusual prevalence of poliomyelitis in and about Boston during the latter part of the summer of 1893. Twenty-six cases had come to his notice during that season.

That a disease occasionally prevails epidemically suggests a specific poison, a definite toxin, and this phase of the etiology of poliomyelitis has recently received attention from foreign observers as well as from Dana, Putnam and others in this country. Thus far, however, there does not seem to have been any substantial progress made toward isolating any specific microorganism peculiar to this disease.

Our epidemic with that of Medin suggests, though on purely clinical grounds, the possibility of such a cause. The unfortunate absence of an autopsy in our cases, though strenuous efforts were several times made to secure them, prevents us from throwing any light on this part of the subject. That domestic animals suffered with human beings in our epidemic is a noteworthy fact and one, so far as I can learn, hitherto unobserved. That such was the case can not be doubted. It has long been known that animals were often attacked by meningitis during an outbreak of that disease in epidemic form. Poliomyelitis has been produced artificially in rabbits and guinea-pigs, but so far I have been unable to find an instance of its spontaneous occurrence simultaneously with the disease in man. This fact again emphasizes the possible infectious character of the disease and lends additional interest to the epidemic here recorded.

DISCUSSION.

DR. J. F. BURNSHED—The paper of Dr. Caverly I consider to be one of very great importance because it deals with an epidemic which will go down in history. This epidemic was not confined to Vermont. Where I lived in New York State, we had what I considered to be an epidemic of poliomyelitis at the same time as that which existed in Vermont, and it was a matter of much concern to us until the literature began to come in.

RIGHT HEMIPLEGIA WITH APHASIA—A CASE.

Read in the Section on Neurology and Medical Jurisprudence, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY H. M. LASH, M.S., M.D.

INDIANAPOLIS, IND.

On Nov. 14, 1894, about 12 m., Mr. L., age 35, married, habits excellent, health previously good, was, without any warning or prodrome, while sitting at his office desk, stricken with complete loss of the use of the right side and with entire loss of voice.

I reached him at 12:40 p.m. Dr. J. T. McShane, who was with him, had noted his condition and had prescribed for him. He had then recovered, in part, the use of his hand, so that he could write his name, as he did to some checks and several letters which he had that forenoon dictated. With a little help he could use his leg sufficiently to walk out to the street and get into a carriage. Soon after he did so, however, he again lost the use of both the arm and the leg. This condition remained until just before the carriage reached his residence, when he recovered for the second time the normal use of them, and got out of the carriage and walked unaided into the house. This was at 1:15 p.m. So far he had not spoken, but had uttered a slight unintelligible sound when the motion of the limbs returned the second time. His overcoat was removed and he lay down upon a couch. Within a few minutes after doing that, his voice came back and he was able to converse in his usual manner, and talked the situation over with me in an intelligent way. But this lasted only about twenty minutes, when the hemiplegia and aphasia both returned with their full force. Aside from the loss of the use of his right arm and leg and his voice, there was no other abnormal condition present. There was no loss of sensation, partial or complete, in any part of the body. His intellect was unimpaired. He understood and knew the meaning of words, and made correct answers by nod or shake of the head to all questions asked. His tongue protruded readily and in a straight line. His sight and all other special senses were undisturbed. The reflexes were all normal. He did not appear to be sick in any way; had not felt dizzy, and at no time had he been for a moment unconscious.

He was put to bed and quiet enjoined. I visited him at 7 p.m. At that time found the temperature 99.6 degrees F., pulse 86. Complained of some dyspnea, and had to be propped up in bed. His urine had passed freely. He could make himself understood by using a few simple words, such as "yes" and "no." Next morning at 7:30 I saw him again. His sleep had not been very good; had been troubled a little with dyspnea. Speech better. Was called at 3 p.m. Had to use a catheter, and this was kept up each day until Nov. 24. Temperature and pulse normal; neither were afterward abnormal. Ordered saline cathartic. Bowels responded and their action was easily kept up from that on by enemas. Dyspnea had disappeared and he was not again troubled with it. His speech gradually improved until on January 1 he could talk almost as well as usual.

The first appearance of motion in the right leg was on Nov. 24, ten days after the attack, when it was found that he could move the toes and foot a very little. On Nov. 26, he could move the entire leg, but to a very limited extent. On Dec. 12, he began sitting up and could then bear some weight on the right leg and take a few steps. Christmas day, with a little help, he walked to the dining room. The improvement has continued, and he now walks about very well with the aid of a cane.

The first indications of motion in the arm were noted on Jan. 1, when he could make some use of the biceps and triceps muscles, slightly flexing and extending the arm. On Jan. 24, it was found that he could use the thumb and index finger a very little, and that there was increased muscular action of the upper arm muscles.

On Feb. 6, improvement in the use of the right thumb and index finger, as well as the whole arm, was observed, and he could slightly move all the remaining fingers on the right hand.

This is quite a well-defined case of right motor hemiplegia with ataxic aphasia, having a strong tendency toward recovery. The improvement has been gradual but steady, and is still going on. The prognosis, therefore, may be regarded as fairly favorable.

In regard to diagnosis, there is very good ground for differences of opinion concerning the nature and seat of the lesion. It must be conceded, however,

that it is cerebral, and located somewhere on or in the left side of the brain.

My own diagnosis on the beginning of the trouble was an embolism of the left middle cerebral artery. I have found no reason since to change it. In my judgment it is a typical and clearly marked case of that condition. The suddenness of the attack and its purely motor character, pointed to the left cerebral motor area and Broca's center as the seat of difficulty.

Hemiplegia may result from cerebral or high up cord lesions. If from cerebral lesion, the paralysis is on the opposite side of the body; if from spinal lesion, it is on the same side. This is the rule, and to it there are very few and rare exceptions.

The hemiplegia from intra-cranial lesions may result from apoplexy or brain clot, tumors, softening, abscesses, traumatic or inflammatory compression, thrombosis and embolism.

A brain clot may be cortical or subcortical. If subcortical, it may be located in the white substance, the basal ganglia, the internal capsule, the motor bundles of the crus and pons, or in the anterior pyramids of the medulla. These are all entitled to consideration in the general discussion of this question, but the method of reaching the right cause in a given case, as in the one reported, must be by exclusion.

In the case presented, the cause is not a cortical surface clot, because it is not likely it would occupy so much space and select only the motor area and Broca's center, without producing other and striking manifestations of its presence.

There is probably not a subcortical clot because in that event there would likely be disturbance of sensation of some of the special senses, particularly that of vision, an implication of the facial muscles, with mental aberration, loss of consciousness and muscular rigidity. This observation applies to any of the subcortical tracks or basal ganglia.

It is difficult to conceive of any of these that would cause only the motor paralysis on one side. The possible exception might be a lesion of the internal capsule. Motor fibers, sensory fibers, fibers of the speech tract and fibers of the optic tract pass through the internal capsule. A lesion might only affect the motor fibers. But as the relation of these fibers from before backward is as follows—viz.: (1) motor fibers, (2) sensory fibers, (3) fibers of the speech tract, (4) optic fibers—it would be next to impossible to have a lesion there producing only motor paralysis and motor aphasia without some disturbance, to say the least, of sensation and probably vision. And then the speech difficulty would more likely be a paraphasia instead of an ataxic aphasia.

A lesion of the basal ganglia lying on either side of the internal capsule, if sufficient to press upon its fibers, would produce similar results.

A lesion in the pons or medulla would produce, besides hemiplegia, hemianesthesia, incoördination, strabismus, facial paralysis, paralysis of the third and seventh nerves, difficulty of deglutition, irregular respiration, convulsions, coma and death.

Tumors, softening, abscesses and inflammatory products are really excluded from the discussion of this case, because there is no history of any brain disease or indication of it whatever. So also of thrombosis, in which there is a gradual occlusion of a blood vessel caused by the development in the vessel at a fixed point of an obstruction that finally fills it up

and cuts off the circulation, which is attended by prodrome and evidences of brain disease.

Motor aphasia is due to a lesion of the third frontal convulsion—Broca's center—or a cutting off by pressure or otherwise, the fibers of the motor speech tract.

In the case mentioned, if there was only motor aphasia without hemiplegia, I think we could only conclude that the difficulty was with Broca's center, for the reason that at no other point could a lesion exist, producing ataxic aphasia without complications.

In our case there is a pure motor hemiplegia of the right side and a true motor aphasia. A consideration of either separately would lead to the opinion that the cause was cortical. That view is certainly greatly strengthened when they are considered together, since it is reasonably certain that they could not have any other common acting lesion.

Broca's center and the left motor area of the cortex are supplied with blood from the inferior external frontal and the ascending frontal branches of the left middle cerebral artery. They have a common point of origin, and sometimes the inferior external arises from the ascending frontal. An embolus at that point would cut off the arterial circulation to both areas and thereby arrest the function of each at the same time. Apparently this is just what occurred to our patient.

As to the source of the embolism I am in the dark. Dr. Theodore Potter at one time saw the case with me, and we were unable to find any disease of the heart or blood-vessel leading toward the brain.

The progress toward recovery in such cases is given as follows: 1. Return of speech. 2. Motion in the leg, beginning with the toes and foot. 3. Motion of upper arm. 4. Motions of fingers and hand. Precisely just this course was taken in the case reported.

The circulation to the center of Broca, was probably reestablished, first partially, and secondly quite completely, by release of that arterial branch from the obstruction. Collateral circulation seems to be taking place in the motor area. The arrangement of the arterial blood-vessels in this part of the brain would favor its establishment in the order already named, and thus explain the steps toward recovery. Whether this patient will regain perfect use of his limbs is a matter of some doubt. That he will, at least, have fair use of them is already assured.

Beside the strictly motor character of the one-sided paralysis and the loss of speech, in this case, there are several other accompanying interesting points to be noted.

Because of the favorable arrangement of the vessels, the left middle cerebral artery is the favorite seat of an embolism—another argument in favor of the diagnosis in this particular case.

The interrupted or wavy character of the trouble at its incipency may be accounted for on the theory that the arterial plug had not yet become so fixed or wedged in its position as to prevent, when it changed its location, the flow of enough blood to the areas to nourish them during the intervals of return of speech and motion.

It has been noticed all along that such acts as yawning or stretching produced marked feelings of motion in the paralyzed limbs. Gowers explains this on the ground of associated movements. A distinct effort to do something with the unaffected hand or foot causes a similar effort in the corresponding paralyzed limb.

The retention of urine for a time I attributed to the shock the brain received, and to the recumbent position he was required to maintain.

The treatment for the first few weeks was light doses of bromid of potash, care in diet and absolute quiet. Later he was given iodid of potash in doses of 5 to 7.5 grains, three times a day for several weeks.

Recently there has been very little medication. The use of the faradic current and massage were begun at proper time and are still being kept up.

18 East Ohio Street.

DISCUSSION.

DR. F. W. LANGDON.—This paper is one of considerable interest and brings up questions that we frequently have to decide as to the location of a lesion and the ultimate prognosis of the case. Being a young man the prognosis is of much more importance than if it was a more or less senile patient, and I think those cases require really much more care on account of the different conditions which prevail in the two classes of patients, the young and the old. The Doctor says the patient is thirty-five, and probably by reason of not reading the full paper we are not informed as to whether there were other lesions which might contribute very materially to a more exact diagnosis, as for instance a preceding rheumatism leaving an endocardial condition which might be the source of an embolus which the Doctor has assumed affects the middle cerebral artery. Other conditions which might produce a cortical lesion would be syphilitic endarteritis with thrombus resulting. In the absence of definite history in these respects, I would say that while the Doctor's diagnosis is quite definite as regards the side of the brain affected, I should be inclined to consider the possibility if not the probability of the lesions being sub-cortical rather than cortical. We have an involvement of areas which, if the lesion was cortical, could hardly fail to be attended by marked mental impairment, by convulsions and active symptoms of cortical irritation at the start, which, if I understand aright, were absent. Again, there are apt to be meningeal symptoms following a cortical lesion if there be a hemorrhage. I should be inclined to exclude the cortical lesion in this case. A sub-cortical lesion can be considered of a very limited character. There may be rupture of a blood-vessel or a thrombus, with small irritation. The suddenness of the attack might exclude a thrombus, but while it might favor the embolic theory, the embolus must be very small. It would seem as if the symptoms must be accounted for by an exceedingly limited involvement in the area of the internal capsule.

WAS HAHNEMANN INSANE ?

Read in the Section on Neurology and Medical Jurisprudence, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY W. W. PARKER, M.D.

RICHMOND, VA.

Nothing but a high sense of public duty will justify a man in attempting to prove another insane, it matters not whether he be dead or alive. The great leading men of the past belong to their posterity. They are valuable lessons to the young, both as warnings against evils and incentives to duty. Biography has always been interesting to me. When nine years old I had read "Plutarch's Lives" more than once. From this kind of study we select our ideals. For this reason the Bible is an invaluable book; it presents us with so many noble ideals on all great moral questions. Some three years ago I read a pamphlet on "The Rise and Decline of Homeopathy," before our State Society, which has had quite a wide circulation. Last year I had a newspaper discussion with the homeopaths of Richmond. Each fired a gun and retired from the field. These things have caused me to study more closely Hahnemann's character, and his unique dogmas. The hot and cold water cures had some common sense in them, but were narrow and on the one-idea theory. Homeopathy, as I

stated in my essay, is transcendentalism; it is not physics, but metaphysics. Hahnemann was a hard student, honest doubtless, and a lover of his kind. His character is above reproach; he was in no sense a quack. His insanity was of a "delusionary" character, well known to alienists. Dr. Young would have called him "a dreamer of gay dreams." True, medicine is practical. We speak of it "as the practice of medicine," not the theory of medicine. Some men are even pleased to call medicine an "art" and not a "science." Too much theory has been the bane of practice. Medicine began with experimentation. However carefully made, experiments must yet be received with great caution. There should be great care also in generalizing from doubtful premises. This error has caused the world much sorrow. We have only to read the numerous pamphlets circulated through the mails to-day with hundreds of certificates of medical men of the marvelous effect of some new drug, to be satisfied that the day of hasty conclusions has by no means passed.

Hahnemann was a singular man. He practiced medicine twenty-eight years and changed his residence twenty-three times. He must have been an unsuccessful practitioner. Perhaps he did not stay long enough in one place for his infinitesimal doses to do their work. By his method it would take a year or two to get one drop of laudanum into his patient's system. A delusion is perverted idea on any subject. It is a very common form of insanity. Some years ago I met a lady at McBride's Private Hospital in Philadelphia, who took me to a door leading into an adjoining room, and said her husband was nailed up in the door casing. I did not attempt to argue with her, as I saw at once she had lost her reason. Hahnemann's "delusion" was on the subject of numbers and forces. He had lost the relation of weight and measures, of little and big, of great and small, of dynamics and statics. To say the smaller the dose—the nearer it was to nothing—the greater its effect, if given in infinitesimal doses, is absurd upon its face, to a man of common sense; to say that only a billionth drop if given every ten minutes will have a better and more certain effect than if given in one drop doses, two or three times a day, is gratuitous; besides, there can be no way possible of proving the proposition. The only way to convince a man holding these absurd views is to satirize him. This Hood and Holmes and others have done:

Well, Doctor,
Great concoctor
Of medicines to help in man's distress;
Diluting the strong to weak
And making ev'n the weak more weak,
"Fine by degrees, and beautifully less."

Suppose a felon doomed to swing
Within a rope,
Might friends not hope
To cure him with a string?
Suppose his breath arrived at a full stop
The shades of death in a black cloud before him,
Would a quintillionth dose of the New Drop
Restore him?

But would it mend his case
To be decillionth dosed
With something like the ghost
Of an emetic!

What shall support the body in its trial,
Cool the hot blood, wild dream, and parching skin,
And tame the raging malady within—
A sniff of Next-to-Nothing in a phial?

Dr. Oliver Wendell Holmes has also satirized him.

I do not remember whether the following is from him or some other American poet:

Take a little rum,
The less you take the better,
Pour it in the lakes of Wenner and of Wetter,
Dip a spoonful out,
Mind you don't get groggy,
Pour it in the lake of Winipisogee,
Shake the mixture well—
Lest it prove inferior,
Then put half a drop
Into Lake Superior.

Every now and then
Take half a drop in water;
If not better soon,
At least you ought to.

What is insanity? An expert says: "It is a delusion or a false concept, an idea which is the product of defective data and defective reasoning and held in spite of the presentation of corrected data and corrected reasoning. This distinguishes it from a common delusion, an error of belief remediable by suitably put evidence." A more simple definition it seems to me would be this: A perverted understanding habitually, though not necessarily at all times, or on all subjects or objects, ignoring common sense and observation, and the plainest relations between cause and effect. The delusion may be upon one subject only.

Were I to see a man driving a nail in the fence and find him tapping it with great delicacy for two or three hours, and were I to say to him, "give the nail two or three vigorous blows and you will do the work," and were he to reply, "this is the best plan, I am satisfied of it," I would at once consider he was insane. Were I to find a man watering his garden with a small watering-pot and only putting one or two drops on each plant, and I should urge him that he was not half doing the work, and he should reply, "the smaller the quantity the better," I would be certain he had lost his reason. Or were a man to claim that two pounds of guano to the acre was better than one ton, I would conclude he was insane. These men might be sound on plowing and cultivating their crops, but certainly unsound upon the quantity of water and guano. If a man were to tell me he was going to London and say that he had but five dollars, and that was enough, I would say at once he was crazy. To say in physics that the nearer you get to nothing, the greater will be the effect and power, is to state an absurdity on its face. Hahnemann said that the nearer you got to the "spiritual" or non-visible or non-ponderable, the greater the power of the drug on the sick man. Is it possible for any man to propound a more absurd proposition in physics? The argumentum ad absurdum is the only mode of replying to such reasoning. Hahnemann had perhaps seen too much physic used, and concluded if he could by some gentle process carefully insinuate his medicine imperceptibly into the system it would less disturb the economy and have better results.

The human body is a strong, well-built machine, enduring great strain and fatigue, and is affected like all other machines by physical agents. We know that one drop of castor oil will not purge, while one ounce will; that one drop of ipecac will not vomit, but two drams will. If we want to produce effects we give what we know from trial will produce results in a reasonable time. This is plain, common sense. We know that the germ of smallpox is very minute,

but we have proof positive that in six or eight days it brings on fever. This is demonstration. Under the system of Hahnemann this sort of proof is impossible. His mode of "testing," as he calls it, is not proof. Its effects are too remote and vague. In the present wild search after germs some may think we have proof of the potency of small forces; but Hahnemann ignored pathology, nor did he seem to inquire into the cause of disease. He said, "If you put liquid medicine in a well-stopped bottle and shake it violently for a while, the patient will feel the effect of the drug on his system." No shaking of the bacillus could get it through the glass bottle into the patient's system. Many germs act quickly and powerfully. If it were necessary, I could easily prove that most homeopathic writers and journals have long since abandoned Hahnemann's wild theories. The homeopathic doctors now give real medicine. A druggist in town has a recipe from one of them for five grains of quinin and one-fourth of a grain of opium, but in the use of medicine for family purposes, put up by the New York Drug Company, authorized by the leading homeopaths, there is no medicine in it worthy of the name. A dose of these pills is from two to four, as a rule. I gave to a man as an experiment forty every two hours for ten days without the least effect. I gave what was known as the most active and energetic poisons. The man swore before a notary public he never felt the slightest effect of the medicine, and the truth of his statement was verified by the temperature and pulse, taken every two hours. Had Hahnemann's disciples adhered to his dogmas his school would have long since died out here as it has in Germany and France. (It is now dying out in England.) Common sense had to assert itself. An English homeopathic journal some time ago proposed the union of the two schools, and frankly asserted that no serious case was attended throughout by homeopaths without resort to drugs. I referred in my pamphlet to a 3-year-old child in Gloucester County, Virginia, who took \$8 worth of homeopathic medicine, the entire supply for the whole family for a year, at one time, and received no damage at all. This is another demonstration of the complete inertness of the medicine. There was no cause of disturbance, hence there was no effect.

In conclusion let me say that I am 71 years old, am the friend of all men engaged in the healing art, more so than ever in my life; that I would not willingly hurt any man's feelings or insult his understanding; my whole purpose is to get at what is sound and sensible in physic. We know but little perfectly. I do not remember in my life to have heard any sensible doctor boast of the perfection of his medical knowledge. That was a sad saying of Paul's to his enemies, whom he truly loved and tried to help, "Do I offend you because I tell you the truth?" Would it be just and right to tell you a lie and mislead you? Two years ago, by authority of the Governor of Virginia, I visited all the lunatic asylums in the state at the head of a commission, and can frankly say that in my best judgment, of the 2,000 lunatics examined I did not see one man more lost to reason (in medicine) than Samuel Christian Friedrich Hahnemann. I see it has been proposed to build a monument to him on American soil, and would I be true to my convictions to hold my peace? In no sense is insanity a crime; it is a sad misfortune, exciting our profoundest sympathy.

CHRONIC MIDDLE EAR SUPPURATION COMPLICATED WITH SUPPURATING MASTOIDITIS.

PAINFUL DRESSING AFTER OPERATION UNDER HYPNOTIC SUGGESTION.

Read in the Section on Neurology and Medical Jurisprudence, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY FRANK C. TODD, M.D.

FORT WORTH, TEXAS.

Jessie C., aged 10, was brought to me by her father with the following history: Chronic middle ear suppuration for three years, complicated by a suppurating mastoiditis on either side which had been discharging through large ragged fistulæ. The discharge was profuse, and the child had been obliged to wear a bandage around her head constantly.

The character and chronicity of the affection had caused the child to be very fretful and impatient; though she was not in the least hysterical; and her parents, who were very sympathetic, had humored her to such an extent that she was indeed a spoiled child. The father informed me also that their family physician, who had been directing a cleansing treatment, had been unable to exercise any control over her whatever. Every time he attempted to do anything the child would cry and say she would not let him touch her; whereupon he would give up the attempt and let her go in the same condition as he had found her.

I therefore recognized that I had a very refractory patient to deal with, and I thought that the management of the disease was not going to be the hardest part of the treatment.

And the first day I found that she came to me with the intention of dealing with me as she had so successfully dealt with my predecessor. It was with some difficulty that I succeeded in making any examination this first day, but I purposely took only a superficial survey on this occasion, finishing my entire exploration only after several visits; making her believe, however, at the end of each séance, that I had done all I desired to. Occasionally I had to inflict discomfort or pain upon her, but before doing so I always informed her that there was to be some pain, and when she objected I reminded her of former incidents when I had finally accomplished my purpose in spite of her remonstrances, after which reminder she would allow me to do as I chose. However, up to the time of the first dressing, two days after performing a mastoid operation I had given her little pain, and I had realized in the beginning that when it became necessary to unpack a tightly packed, fresh granulating wound, irrigate, and repack again with gauze, there was going to be considerable pain and much more trouble. It was with this painful treatment in view that I had spent so much time in training my patient to my subjection.

She had fought against the administration of the chloroform preparatory for the operation, and this had aroused in her the old spirit of obstinacy, so that when we got her on the table and things had been made ready for the dressing, we found that we were going to have more than we could do to hold her and accomplish our object. The two female nurses were unable to keep her still, either by mental or physical persuasion; she threw her arms about and kicked fiercely. I could not coax her and she knew that I could not hold her and dress her wound at the same

time, so she resolved to have her own way. But when she saw me come toward her with the evident intention of compelling her to obey, she seemed to lose heart, though she continued to scream loudly and apparently resisted all she thought she could.

I placed my left hand on her forehead and passed my right arm over her body, inclosing her arms, and laid her flat on her back, where I held her as in a vice. I then said, "You can not move; you are fastened down." Seeing that her attempts were feeble, I released my hold and repeated the suggestion. This time there was not even an attempt, and she lay as I held her, but continued to scream. I then said: "Stop crying." She obeyed instantly. Again, I said: "You can not move nor cry, no matter how hard you try." She did neither, while I took time to prepare my hands again and to make a thorough dressing. After I had completed I told her to sit up, as I had finished, which she did immediately. I had told her also that she would feel no pain, and she said afterward that there was none, though the next time I dressed the case, when there would normally have been less, she complained a great deal; this time however it was not necessary to hypnotize her.

This case demonstrates Moll's statement that disobedient people, when hypnotized, are often the easiest to manage.

I have purposely made prominent the fact that this patient was brought under control against her desire and in opposition to her strongest efforts. This is somewhat different from any of the cases you mentioned in your recent article—nevertheless an exemplification of your claim that some people can sometimes be hypnotized against their will.

THE NEURON IN MEDICINE.

Delivered before the Tri-State Medical Society held in Des Moines, Iowa, Oct. 1, 2 and 3, 1895.

BY SANGER BROWN, M.D.

CHICAGO.

Some experience in post-graduate teaching has convinced me that the rank and file of the profession pretty generally believe that neurology consists mainly of an intricate tissue of technicalities which only neurologists can understand, if, indeed, the subject is not past all understanding. It ought to be said that this remark applies more properly to students who passed through college, say, prior to seven or eight years ago than to those who are now passing through; because the science has now advanced so far that much of what before was speculation and hypothesis is now susceptible of demonstration, and both student and teacher have shown a correspondingly increased interest. This has been all the greater, because as the science has unfolded, its importance in medicine has been more and more recognized and appreciated.

It is the purpose of this paper not to trace the science of neurology, step by step, from its humble origin to its present eminence, but simply to direct attention to one feature of comparatively recent development which has gone a great way toward facilitating a clear view regarding the etiology, the pathology and treatment of diseases of the nervous system. This feature consists in conceiving the nervous system to be composed of an aggregation of units very similar in character, and in the thorough study of these units.

It is important at the outset to have a name which

shall appropriately designate this entire unit, and I have adopted Waldyer's term of neuron to which, however Prof. Schäfer of London, objects; and while his reasons for putting forth a nomenclature of his own are sound, I think Waldyer's term is so familiar and its application so readily understood and accepted that it will come into universal use.

Improved methods of staining, together with close application and great natural aptitude on the part of several students, have resulted in demonstrations which have added much to our knowledge of the neuron.

Fig. 1. A projection cell of the cerebral cortex (Schäfer); *dr.*, protoplasmic processes; *n*, axis-cylinder process; *coll.*, branch of axis-cylinder process.

Fig. 1, which represents a cell, the body of which is situated in the motor area of the cerebral cortex, may be taken as an illustration of the neuron. It will be seen to consist of a cell body and two processes. The cell body is seen to contain a prominent nucleus which is large in proportion to the cell body, and the size of both generally bears a distinct relation to the length of the processes which emanate

therefrom. It may be observed here that the nucleus always bears a conspicuous nucleolus.

The processes emanating from the cell body are of two kinds, which are characterized by different names and are certainly quite different in appearance and probably in function. The first and only essential kind is the axis-cylinder process. The other is designated the protoplasmic process and is not essential because many nerve cells are entirely destitute of it.

The axis-cylinder process consists of a long and slender fibril which does not diminish much in size

as it proceeds and, after extending from a fraction of an inch to several feet, ends in a terminal arborization. This arborization may either connect with an ultimate muscular, sensory or glandular element or with another neuron; of this latter connection more remains to be said. Contrary to former teaching these processes have branches, called collaterals, which are given off nearly at right angles and probably end in arborizations connecting them with other neurons.

The protoplasmic process is always comparatively short, has a rough outline, begins to branch close to the body of the neuron and the branches are given off at an acute angle so that the identity of the original fiber is soon lost in the smaller branches.

Though generally the body of a motor neuron is larger than that of a sensory neuron, the neurons of the cerebro-spinal axis have not recently been classified according to this difference; they have been classified, however, according to the number and length of the axis-cylinder processes. Neurons with long axis-cylinder processes, whether motor or sensory, are termed projection cells or neurons, while those with short axis-cylinder processes are called intermediary cells or neurons.

In Fig. 2, 6 and its process is a sensory projection-neuron, and so is 17, but 18 is an intermediary neuron, because it may be regarded as an intermediary link between the centripetal or sensory impressions brought to a nerve center by sensory neurons and the motor or centrifugal impressions which must proceed along 1, 2, 3 and 5, the motor projection cells or neurons.

Fig. 2.—Diagram showing the probable relations of some of the principal cells (neurons) of the cerebro-spinal system to one another (after Schäfer). 1, body of a neuron of the cortex cerebri; 2, its axis-cylinder process passing down in the pyramidal tract and giving off branches, some of which, 3, 8, end in arborizations around the bodies of other neurons in the anterior horn of the spinal cord, the main fiber having a similar ending at 4; *coll.*, a branch passing in the corpus callosum to the cortex of the opposite side; *str.*, a branch passing into the corpus striatum; 5, axis-cylinder process of peripheral neuron in anterior horn passing to form a terminal arborization in the end-plate of a muscle fiber, *m*; 6, body of neuron of one of the spinal ganglia. Its axis-cylinder process bifurcates and one branch, 7, passes to the periphery to end in an arborization in the sensory surface, 8. The other branch bifurcates after entering the cord (at 8) and its divisions pass upward and downward (the latter for a short distance only); 9, ending of the descending branch in a terminal arborization around the body of a neuron of the posterior horn, the axis-cylinder of which again ends in a similar arborization around the body of a neuron of the anterior horn; 10, a branch passing from the ascending division directly to envelop the body of a neuron of the anterior horn; 11, one passing to envelop the body of a neuron of Clarke's column; 12, a branch having connections like those of 9; 13, ending of the ascending division of the axis-cylinder process emanating from 6 around one of the bodies of the neurons of the posterior columns of the bulb; 14, 14, axis-cylinder process of the neurons of the posterior horns passing from an arborization around the bodies of the motor neurons; 15, an axis-cylinder process of the ascending cerebellar tract passing up to form an arborization around the body of a neuron of the cerebellum; 16, axis-cylinder process of this neuron passing down the bulb and cord and giving off branches to envelop the bodies of the neurons of the anterior horns; 17, axis-cylinder process of the neurons of the posterior columns of the bulb passing to the cerebrum and forming a terminal arborization around one of the smaller cerebral neurons, which may be regarded as an intermediary neuron; 18, axis-cylinder process of this cell, forming an arborization around the central projection-neuron 1.

Fig. 3.—A neuron from the superficial layer of the cerebral cortex (after R. y. Cajal). *n, n*, axis-cylinder processes; *dr, dr*, protoplasmic processes.

Continuity of fibers ever so fine have never been observed forming a connection between two neurons. Such a connection must be regarded as a physiologic one and takes place by the adjunction of the arborized process of one neuron with the body of another neuron, or by the adjunction and interlacement of the arborized process of one neuron with a similar process of another neuron, as may be observed in the olfactory glomerule shown in Fig. 4. Indeed, the gray matter in which the bodies of the neurons lie imbedded is doubtless made up of the interlaced fibrils forming the arborizations above described. In cutting through the gray matter numerous points are seen, resulting from a cross section of the fibers comprising these arborizations; hence the Germans have designated it the punkt substance, and refer to it as a highly important part of the nervous system which, indeed it is, since in it a nervous impulse may be transferred from one neuron to another.

It is a general law applicable to every cell that when any part of it is separated from the nucleus that part dies. This applies to the neuron and is not affected by the direction in which impulses traverse the part separated, say the axis-cylinder process. Right at this point, I wish to insist upon the importance of regarding the neuron with all its processes

simply as a cell, no matter how widely it may differ in various respects from the current conception of a cell. When it is remembered that it is the function of the cell nucleus to preside over the nutrition of the cell processes, it can be readily understood how slight a cause affecting the nutrition of this nucleus might affect profoundly the nutrition of the delicate axis-cylinder process at a distance of several feet from its nutritive center.

Though I shall return to it again, I may here call attention, by way of parenthesis, to the probability that lead palsy and diphtheritic paralysis are respectively due to the action of a mineral poison in the one case and a bacterial toxin in the other acting upon the nucleus of the nerve cell.

The essential function of the axis-cylinder process is conduction of nervous impulses. It is pretty evident that in some cases this impulse passes through the body of the neuron, as, for instance, where two axis-cylinder processes emanate from its opposite sides as shown in Fig. 3. But it is no less probable that a nerve impulse may be transmitted the whole length of the axis-cylinder process without traversing the cell body, as may be understood by reference to the neuron 7, 6, 13 in Fig. 2. Indeed, experiments

Fig. 4.—Diagram of the connections between the olfactory sense organs and the brain (Schäfer). *olf. c.*, olfactory neurons sending their axis-cylinder processes, *olf. n.* into the olfactory glomeruli, *gl.*; *m. c.*, "mitral" neurons of olfactory bulb sending axis-cylinder processes into the glomeruli and axis-cylinder processes, *a, a*, into the olfactory tract, *n, n*; *n*, an axis-cylinder process derived from a cerebral neuron ending in the olfactory bulb.

made on the higher vertebrates might be cited strongly confirmatory of this view, while it seems certain that in the earthworm, sensory impulses are brought from the skin to the central nervous system where they are converted into motor impulses without traversing the nucleated body of a neuron at all as shown in Fig. 5.

The view that the nucleated body of a neuron may act as an automatic generator of nerve impulse is very commonly entertained, though direct proof of it is lacking. The so-called automatic action of the respiratory centers in the medulla can not fairly be taken as proof, for this is known to depend upon the circulation through the medulla oblongata of venous blood.¹

¹ For many valuable and interesting facts regarding nerve impulses, and much else of interest regarding the neuron, I refer to the admirable address of Prof. E. A. Schäfer, F.R.S., as President of the London Neurological Society, to which I am much indebted for many of the statements herein made. (See "The Nerve Cell Considered as the Basis of Neurology," by E. A. Schäfer, F.R.S., *Brain*, vol. xvi.)

Though the service which this conception of the neuron renders to psychology can not be regarded as inferior to that which it yields to neurology, I can not at this time consider it in relation to mental operations; but keeping in view the statements already made, I wish to make some practical applications of it to the subject of neurology and will in the first place call attention to a few well-known facts regarding reflex action.

The motor path, from the so-called motor region of the brain to the motor end organs, consists of two neurons or segments, an upper or central neuron and a lower or peripheral neuron. The body of the central neuron is in the brain. The body of the peripheral neuron in the spinal cord, hence the term central or peripheral disease, should refer to the central or peripheral neuron, notwithstanding the central neuron is partly in the brain and partly in the cord, and the peripheral neuron is partly in the cord and partly in the peripheral nerve.

When a movement results from the direct action of the lower or peripheral sensory neuron upon the

Fig. 5.—Diagram of the nervous system of *Lumbricus* (after Lenhossek and Retzlus); *m.*, motor neuron; *i.*, intermediary neuron; *s.*, sensory axis-cylinder processes proceeding from *s'*, sensory neurons in the epidermis.

lower or peripheral motor neuron, such movement is designated by the term reflex; on the other hand, when a movement results from the action of the upper or central sensory neuron upon the upper or central motor neuron, such movement is designated as voluntary, whether conscious or not. In health, the upper or central motor neuron or segment has a marked inhibitory influence over the lower or peripheral motor neuron or segment. Therefore, when the influence of the upper motor neuron or segment is impaired or destroyed by disease, if the reflex arc remain intact the reflexes will be increased. I might explain that by the reflex arc I mean the path which is taken by an impression made upon a sensory apparatus along a peripheral sensory neuron directly to a peripheral motor neuron, and thus outward to a motor mechan-

ism as illustrated by Fig. 2. 7, 3, 5. Disease in any part of this arc will impair or destroy the corresponding reflex.

Before proceeding to apply the facts for purposes diagnostic, it should be stated that the upper segment or central neuron is never connected directly with any end organ, but always with a second neuron; and also that the nucleus of the lower motor segment or peripheral neuron presides over the nutrition of the muscle to which it is distributed. It only remains now to enumerate those pathologic processes which commonly affect these several segments, and first the upper or central motor neuron or segment 1, 2, 3 may be considered in Fig. 2. In the main the processes are traumatism, hemorrhage, embolus or thrombus, tumor, abscess and lateral sclerosis; excepting during the period of severe shock the symptoms due to injury of this neuron would be paralysis and increased reflexes without atrophy; and to this might be added spasm in case of an irritating lesion as a gumma. So far as the ultimate symptoms are concerned, it makes no difference to what part of the neuron the destructive agency is applied.

Next, we will consider some of the pathologic processes which affect the lower or peripheral motor neuron, 5 in Fig. 2. They are acute or chronic inflammation of the cell body in the anterior horn of the spinal cord and also the action of metallic poisons or microbic toxins upon it, transverse myelitis, peripheral neuritis and trauma. The symptoms due to disease affecting this neuron are paralysis, muscular atrophy and loss of the reflexes.

A pathologic process affecting the upper or central sensory neuron, 17 in Fig. 2, would affect sensation but would have no influence over the reflexes. With the exception of chronic degenerative change the same processes as were enumerated as affecting the upper or central motor neuron may affect this one, though the course of its axis-cylinder processes nor the position of the bodies are not so definitely known.

Lastly, the lower or peripheral sensory neuron, 13, 8, 6, 7 in Fig. 2, may suffer in the part of the axis-cylinder above the cell body in the cord from the effects of acute inflammation as in transverse myelitis, and from degeneration as in locomotor ataxia; below the cell body from inflammation (neuritis) or traumatism. If the lesion involve that part of the neuron which serves to form part of the reflex arc, then in addition to lost or impaired sensation there will be lost or impaired reflexes. Where a lesion involves several neurons with different functions the symptoms will be correspondingly combined, excepting of course where the lower segments are involved; there is then no way of interrogating the upper segments.

It remains to apply this conception to diseases affecting the cerebellum and the sympathetic system. While I do not underestimate the importance of these parts of the nervous system, a sufficient number of definite anatomic and physiologic facts have not yet accumulated to render such an attempted application feasible. I can not refrain, however, from calling attention to a very ingenious not to say useful hypothesis which has been recently put forward by Profs. Lepine and Duval, of Paris, and which, from the conception of the neuron, affords a rational explanation of the organic basis for various so-called functional manifestations of the nervous system. Everyone is familiar with the so-called amœbic

movements of cells, and by assuming that, by reason of such movements the contiguity which one neuron bears to another and which is essential to the transference of an impulse is so far broken that such transference does not take place, various phenomena are accounted for; thus in sound sleep such contraction and separation of neurons may be regarded as very general and complete; the upper neurons being almost completely isolated from the lower; while in light dozing and somnambulism a greater or less connection of varying character may be supposed to remain. In simple insomnia, from some obscure nutritive defect, this spontaneous contraction which causes the separation, producing normal sleep, does not occur or may not long enough continue and, similarly, in hysterical paralysis with its sudden recoveries, these amœboid movements or their absence will explain pretty well the phenomena.

It may be supposed that in a normal individual the request to rise from a chair and walk would cause a sufficiently strong impression upon the neurons of the brain ordinarily concerned in mental operations to cause their processes to elongate, and so bring them into such physiologic relation with the lower segment as would set in operation such muscles as might be necessary to the proper performance of the movement, while in a person affected with hysteria such elongation might not occur and hysterical paralysis would be present.

But suppose in this latter case an unusual stimulus be applied to the upper segment or neuron, such as an ignorant, credulous and superstitious person might be conceived to obtain at the hands of a so-called miracle-worker, then the necessary contiguity might result and thus a miraculous cure be effected; inasmuch, however, as according to this hypothesis the paralysis depended primarily upon a defect in the upper or central neuron, it might be expected that such a cure would not be permanent, and experience amply justifies this expectation, for we know full well how frequently recovery from hysterical paralysis is followed by relapse.

I can not at this stage discuss at length the bearing that this conception has upon the pathology of the nervous system, but will cite a few instances where, in my opinion, it is conducive to clearness of view.

In the toxic palsies, unattended with pain, it seems much more reasonable to assume that the poison acts on the body of the neuron than that it has a selective influence for the peripheral part only of the axis-cylinder process. It is at all events manifestly improper to designate these processes by the term neuritis, for none of the characteristics of inflammation attend the process, as pain, heat and swelling. According to this conception it is not fair to assume that the primary lesion in locomotor ataxia consists of disease of the nerve fibers, for in that case it must be maintained that the axis cylinder on one side of and near to its nutritive center degenerates, while that on the other remains comparatively healthy, which is unreasonable. Therefore, the view already held by many that the disease begins in the adventitious tissue and involves the nervous element subsequently finds strong confirmation in this conception.

Recent demonstrations and hypotheses concerning the neuron have done much to render therapeutic measures more rational, if they have not yet developed anything new. For instance, it can be under-

stood how a drug, by causing contraction of the sensory neurons, might abolish pain and even produce artificial sleep. In this connection opium, chloroform, etc., might be mentioned.

In the so-called toxic palsies, whether the toxin is supposed to act more intensely upon the part of the axis cylinder that degenerates or upon the body of neuron is not material, the therapeutic problem is the same, namely, to prevent the further formation or introduction of the substance into the system and promote the elimination of that already present.

If it is a fact that locomotor ataxia begins as a proliferation of the connective tissue in the spinal cord and affects the nervous elements secondarily, then direct stimulation to the spinal cord by means of electricity, with a view of promoting the nutrition of the defective tissues and thus their return to health, is an eminently rational process. Enough cases have been reported where strong galvanic currents to the spine have produced a myelitis, to make it certain that a proper degree of stimulation may in this way be applied. So that recent researches tend to support the assertion made some time ago by my distinguished colleague, Dr. Dr. R. Brower, at the International Medical Congress held in Copenhagen, that the he had treated cases of locomotor ataxia successfully by the application of strong galvanic currents to the spine, although when he made it it was received in some quarters with considerable skepticism. Though some effort may be required on the part of those who learned their neurology before these demonstrations and hypotheses were brought forward to recast their conceptions in accordance with the new order of things, I think whoever makes the attempt will be amply repaid, and, so far from finding his work obscure and unsatisfactory, will find it fairly clear and interesting.

THE VALUE OF SHARP CURETTES IN THE REMOVAL OF SEPTAL PROJECTIONS.

BY HANAU W. LOEB, A.M., M.D.

Professor of Diseases of the Nose and Throat, Marion-Sims College of Medicine; Surgeon to the Nose and Throat Department of the Rebekah Hospital, and Missouri Pacific Hospital.

ST. LOUIS, MO.

Many and various are the mechanical plans and devices for the treatment of cartilaginous and bony projections from the nasal septum. Not unnaturally, for the great influence which these conditions have upon the pathology of the nose is a matter of such positive scientific acceptance, that inventive genius in this particular is properly stimulated.

While within the short compass of a paper one could not be expected to give a complete review of the various instruments, it may be well in connection with the subject of the paper to glance at the more important instruments devised for the removal of septal projections, ridges, spurs, and the like. The literature of this subject is very striking, in one particular especially; viz., that deflections of the septum and exostoses and ecchondroses growing from the septum are considered by most writers as if they were identical conditions. They have many points in common; their pathology, however, is unlike; at least no one seems to have fully solved the problem of their relationship. Their treatment is so manifestly different that much confusion, at least to the inexperienced, would be obviated if the two conditions were considered under different headings.

For this reason septal deflections are ignored in this paper and reference is made to the treatment of spurs and ridges alone.

MacDonald¹ advises a linear incision over the projection, followed by turning up the perichondrium with a raspator, and removal of the superabundant cartilage with a saw or gouge. He considers a trephine preferable for the removal of small spurs. It is undoubtedly true that it is better to remove these small spurs with a trephine than by the means advocated by MacDonald; there are, however, certainly more satisfactory instruments for this purpose than the trephine.

The same author recommends certain forms of gouges which act in a somewhat similar way to the instrument about to be described in this article. A double set (right-sided and left-sided) is required—a decided disadvantage. These gouges are of service, yet they are manifestly unequal to the sharp curettes in strength, simplicity and accuracy of operations.

The practice which Jarvis² recommends, of transfixion and snaring, is not readily applicable to many cases, and when it is used the operation is needlessly prolonged.

Seiler's dental engine³ and Curtis' electro motor⁴ have accomplished much in making the removal of septal projections a matter of little difficulty and technique. Some cases, however, do not admit of this form of operation; in addition many rough places frequently remain upon the septum, however careful the operator may be. To this fact numerous writers have testified. In this connection it may be well to mention that Jarvis⁵ insists that nasal drills should be used with great circumspection. No instrument which operates like these drills and trephines can be expected to leave a smooth surface where tissue is no denser than that of septal projections. If the spur or ridge were as hard as the teeth, it would be a different proposition; then such instruments would be ideal as they are in dental work. To clear away the rough places remaining after these operations, the instruments presented by the writer are very pleasing, so that by using the motor first, and the sharp curettes afterward, a most perfect result may be obtained.

Seiler advocates a method not very different from that of MacDonald. He cuts away the mucous membrane and then with a gouge and mallet removes the projection. Cheval⁶ mentions a gouge with a handle at 90 degrees to the shaft, which he considers useful to trim down projections. The handle being at right angles there is no interference to the view.

The most serviceable instrument in the great majority of cases is the saw devised and popularized by Bosworth.⁷ With it the operation may be most expeditiously performed, a smooth surface almost invariably remains and healing is rapid.

There are, however, many projections from the septum for which from their very nature saws are not applicable. Many present too obtuse an angle to the septum, while others are too far from the anterior nares, either posteriorly or superiorly. Some are situated beyond a deflected portion of the septum, which prevents a proper application of the saw.

⁷ Diseases of the Nose and Throat, 303.

Still others are so small that one can not obtain sufficient purchase for the saw. What is true of the saw is also true of the other instruments which have been mentioned. In all these cases the instruments devised by the writer come into play. They are not unlike the ordinary uterine curettes in form, but being highly tempered and sharpened they are readily capable of cutting the cartilaginous projections from the septum. Several varieties have been used, differing slightly in shape, size and inclination to the shaft.

The principle is the use of a circular or straight blade from 2 to 6 mm. long, attached to the shaft in such a manner that an opening remains for engaging the offending projection. Where the circular blades are used, the opening appears as a triangle with a concavely curved base; with the straight blades it is almost a straight triangle, the most acute angle being toward the shaft.

The cut which accompanies this paper shows their character and appearance. The curettes have been made by the A. S. Aloe Company, St. Louis, whom I must thank for assistance in the experimental stage of these instruments. They will be found very useful in the removal of small spurs especially, one application of an instrument being frequently sufficient. The operator will be pleased with the rapidity of the operation and the smoothness of the surface which remains after the application of the instrument.

Spurs that are high up are easily reached and removed. Projections forming an obtuse angle with the septum are excised with ease and convex ridges are trimmed down with great rapidity. It is sometimes necessary to use the curette several times, taking off a small slice of the cartilaginous projection at each effort. When spurs far back are to be removed the curette is especially indicated. In this particular at least no instrument in my hands has ever been so satisfactory. After sawing, drilling and trephining, nothing is better for paring off the rough edges, as one may be sure that a smooth surface will remain.

The force used must be a pulling force which can not be considered in anywise objectionable. The amount to be used must be gauged according to circumstances, a matter, however, which will require no study on the part of one familiar with nasal operations.

In elderly persons, the instruments are quickly dulled on account of the calcareous nature of the tissue to be removed. The same thing takes place in projections from the bony septum of younger adults. It is therefore often necessary to re-sharpen instruments, but as this may be done without difficulty there can be no serious objection upon that score.

An important consideration is the ease with which these instruments may be cleansed and sterilized.

There are no rough surfaces to which general surgeons entertain such disapprobation; every portion is susceptible to thorough aseptic procedures.

I have not found it necessary to use handles at a right angle to the shaft, as advocated by MacDonald, Cheval and others. So far, at least, a handle in the same plane as the shaft has not seemed to interfere with vision. It is doubtful if right angle handles would be as serviceable as a straight handle, from the fact that the availability of the instrument greatly depends upon the precision of the pulling force which the operator exerts.

The amount of hemorrhage that occurs does not differ, so far as I am able to judge, from that occasioned by any other instrument for similar purposes. The instruments may be used on either side of the nose, the anterior, posterior, superior or inferior part of the septum.

My observations lead me to believe that it is unnecessary to take the mucous membrane into consideration, unless an unusually large amount might be removed. The scabbing which sometimes follows septal operations seems to be more dependent upon the lack of smoothness of the surface after operation than upon the coincident removal of the mucous membrane.

After an experience of five years, I consider that I am justified in presenting this for my colleagues'

consideration. I do not, however, desire to place myself in the position of advocating that these instruments should replace others in septal operations, for I make frequent use of almost all that have been suggested. I simply present these as being worthy of use in the special class of cases enumerated in this paper.

3536 Olive Street.

ILEUS.

CHICAGO.

The subject of intestinal obstruction has always been one of great interest and will continue so until our methods and results in diagnosis are greatly advanced. Before entering into the details of the subject, let us take a view of the mechanism of the intestinal tract from the pylorus to the sphincter ani. We have here a long muscular tube of varying size with natural constrictions in certain positions, either from *a*, a special muscular development (sphincters), or *b*, from abrupt changes in the course of

the canal (flexures), or *c*, from gradual diminution in the size of the canal, as of the lower end of the ileum. This canal has, besides its physiological functions those of secreting, absorbing and excreting, the power of propelling its contents by its own muscular contraction. It can readily be seen that a fecal stasis could be produced:

1. By the absence of muscular contraction—paralysis. This paralysis may be of spinal origin, may originate in the afferent nerve, or there may be a local paralysis, as from infection at the terminal filaments.

2. From tonic contraction, as from mineral poisonings, lead and from certain ptomaine poisoning, as tyrotoxin.

3. It may result from mechanical causes, as constriction in the calibre, bending at a sharp angle, occlusion by a foreign body, as a gall-stone or a neoplasm; compression from without, etc.

With this short consideration of the mechanism of obstruction we will take up the subject of ileus in general. By the term ileus is meant not a definite pathologic entity, but a complex of symptoms produced by very different causes. The characteristic symptoms of ileus are abdominal pain, inability to produce bowel movement, vomiting and meteorismus (tyimpanites). These symptoms may be produced by adynamic, dynamic or mechanical causes. We have therefore adynamic, dynamic and mechanic ileus.

ADYNAMIC ILEUS

Is always the result of paralysis of a larger or smaller portion of the intestine from the following causes:

1. Paralysis from extensive operations on the mesentery, disturbing its circulation.

2. Paralysis of a loop returned after prolonged strangulation, particularly from femoral hernia.

3. Injuries to the spinal cord, as fractures, bullet wounds and punctures.

4. Injury to the afferent nerve.

5. Reflex paralysis, as that produced by the passage of gall-stones into the ducts, renal calculi, strangulated omentum or compression of an ovary.

6. Septic paralysis from peritonitis, cholecystitis, salpyngitis, embolism of mesenteric artery, etc.

In the first class, where extensive operations have been performed on the mesentery for the removal of tumors, the repair of lacerations, etc., there is always danger of paralysis and gangrene of the dependent coil as a result. I have endeavored to determine by experiment to what extent we are permitted to resect or destroy the circulation in the mesentery, without endangering the bowel, with the following results:

Experiment 1.—Large dog; aseptic laparotomy; ligation of the mesenteric vessels supplying three inches of the intestinal tract, after having emptied the intestine and ligated it so as to occlude its calibre, being careful not to include the parallel artery of the bowel; abdomen closed. Examination forty-eight hours later showed the intestine in good condition. The same experiment was repeated, and it was found that when a

Fig. I

greater segment than six and one-half inches was included in the ligatures, gangrene took place on the convex side of the segment near its center (Fig. 1). This shows that the parallel vessel will supply the intestine with sufficient blood to retain its vitality for forty-eight hours, even though the mesenteric supply were completely shut off for that length of time.

Experiment 2.—Ligation of the mesenteric vessels and the parallel vessels of the bowel, without closing the caliber of the bowel, could be made to the extent of one-half inch. When more than this was included gangrene ensued.

The following is of interest:

Experiment 3.—Dog; aseptic laparotomy; mesenteric vessels ligated, supplying a segment of seven inches; segment

Fig. II

emptied; parallel vessel and intestine ligated (Fig. 2). □ Dog died forty-one hours after operation. Post-mortem: The ligatures around the intestine were still in position, the contents had not escaped. The segment resembled a blood clot, and all evidences of organized tissue had disappeared (Fig. 3). The disintegration was so complete that I can not attribute it to any other cause than auto digestion. The peritoneum was universally denuded of its endothelium and the cavity contained a considerable quantity of blood.

It is shown by these experiments that the parallel artery must be given the greatest consideration in

operating on the bowel and mesentery. When it is injured, as by a bullet or in an operation, resection should be made of that portion from which its blood supply is cut off.

Ileus following the return of a bowel that has been strangulated for a considerable time, and particularly the severe strangulation of femoral hernia, is due to thrombosis of the veins, a local paresis or ischemia from the occlusion of the parallel artery, and not infrequently causes a fatal termination in cases where appearances promised a restoration to the function of the bowel when returned. This form of ileus must not be confounded, however, with that following reduction of hernia *en bloc*, which will be considered later.

A rare cause of ileus is an embolism of the mesenteric artery, producing an ischemia, paralysis and gangrene.

Pathologic lesions and injuries of the spine, as fractures, produce a paralysis of the intestine, followed by great meteorismus, which may continue for several days after the injury. It is one of the most unpleasant complications following fractures of the spine. The abdomen becomes enormously distended; interferes greatly with respiration, and may even produce prolapsus recti. Under favorable conditions it subsides on the fourth or fifth day after the injury. It may also be caused by spinal hemorrhage following traumatism without fracture.

Fig III

The following case illustrates:

Male, age 32, brought to Cook County Hospital; history given as follows: In a quarrel a few hours previous patient was shot in the neck from the front; immediately following the discharge of the gun, he fell to the floor paralyzed and remained so, though he was quite conscious. Examination: A small bullet wound just outside the cervical vessels and an inch below the angle of the jaw; there was no wound of exit; the paralysis of all the extremities was complete and he was aphasic; thirty-six hours after he became unconscious; his respiration was purely diaphragmatic; his abdomen became enormously distended and peristalsis was absent; priapism was marked. These symptoms continued until the end of the fourth day when he succumbed. Diagnosis: Penetrating bullet wound of cervical portion of spinal cord. Post-mortem showed the spinal canal full of blood extending its entire length and compressing the cord. The tympanitis in this was extreme. I firmly believe an operation would have saved this man, as death was caused by compression of the cord with blood.

Injury to the afferent nerve supply, as a blow upon the epigastrium, may produce a paralysis and all the manifestations of obstruction; a bullet wound in the mediastinum may have the same effect, as is illustrated in the following case, which occurred during my service at Cook County Hospital in the spring of 1890:

A police officer was pursuing a burglar upstairs when the latter turned and fired downward. The bullet passed into the mediastinum at the right sterno-clavicular junction. There was no evidence of injury to the lung, large blood-vessels nor

stomach, but the patient gradually developed the symptoms of ileus; pain in the abdomen, not severe; slight tenderness; vomiting persistent; enormous distension of the abdomen; complete absence of peristalsis; inability to produce bowel movement. These symptoms continued for seven days; patient's pulse was then 140; temperature 99°; respiration 46; facial expression bad, and death seemed imminent. Diagnosis: Perforative peritonitis. Laparotomy. The intestines enormously distended, but not congested in the least; no inflammation at any place in the peritoneum; a small quantity of transuded serous fluid was present in the most dependent portion of the cavity. The fluid contents of the bowel gravitated with alteration of position and explained the cause of the change in the location of dullness noticed before operation, viz., that dullness was present always in the dependent portion of the abdomen, but the operation showed it was not due to free fluid in the cavity, but to fluid that gravitated to the dependent portion of the intestine on account of the complete paralysis. The abdomen was closed. The stimulation of the operation produced an active peristalsis, which was soon followed by the passage of gas and feces; vomiting ceased, pulse improved, facial expression changed, and the patient made a rapid and uneventful convalescence. This is a typical case of ileus from afferent nerve paralysis.

Reflex ileus may be produced by: *a*, Strangulation of omentum; *b*, gall stone obstruction in the cystic or common duct; *c*, impaction of renal calculus in ureter, and *d*, by compression of an ovary.

In strangulated omentum the symptoms of ileus are very pronounced and continue for a considerable time in the early stages, and it is difficult to make a differential diagnosis between it and mechanical obstruction of the intestine.

In obstructions to the cystic or common duct the symptoms of ileus are also pronounced and continuous. I have in the last two years seen three cases in which the patients were prepared for laparotomy for intestinal obstruction where this condition existed in the cystic duct. Ileus from renal calculus is of shorter duration than the other varieties mentioned.

Occasionally an ovary is compressed between the bony wall of the pelvis and a fibroid or other tumor, producing the symptoms of ileus, which continue with greater or lesser severity until the ovary is released.

Ileus from sepsis or infection ileus: *a*, peritonitis general; *b*, peritonitis local. The peritonitis may be of chemical or bacterial origin. An infection of the peritoneum can occur from a perforation, through impaired resistance of the wall, as an ulcer in the appendix or intestine, through a diseased tube or gall bladder, or from a suppuration contiguous to it. We have in the peritoneum as a result of this infection either an acute, rapidly destructive type, where the symptoms of obstruction are pronounced at the onset and continue until a few hours before death, when relaxation takes place and there are frequent fluid bowel discharges. This is characteristic of peritonitis, and does not occur in mechanical obstruction. The post-mortems show the peritoneum red, denuded of its endothelium, with but a small quantity of exudate and no flakes nor pockets of pus. There are multiple capillary hemorrhages, the gloss is absent and bowel greatly distended. This is the variety which occurred very frequently after operations in the peritoneal cavity in the pre-antiseptic period, but now, fortunately, it is very rare.

In the subacute and circumscribed inflammations of the peritoneum the symptoms of ileus are less pronounced and pass away in about forty-eight hours after the onset of the attack. In these cases the laparotomies and post-mortems show the bowel covered with a fibro-purulent exudate, many adhesions and often circumscribed accumulations of pus. The more

acute the attack the more the pathologic phenomena manifest themselves. The infiltration of the intestinal wall produces a paralysis of peristalsis, and the more virulent the poison the more complete and lasting the paralysis.

Uremic ileus.—In one of the varied forms of uremic manifestations—the intestinal variety—we have symptoms very clearly resembling those of mechanical intestinal obstruction. The physical signs of intestinal obstruction, as increased peristalsis, tympanites, circumscribed areas of dullness are absent, while the vomiting and inability to produce bowel movements are persistent. No other uremic symptoms may be present to suggest the diagnosis, but an examination of the urine demonstrates organic disease of the kidneys. It must be remembered that intestinal obstruction can occur in an uremic and, on the other hand, that a small percentage of albumin is often present in mechanic ileus.

DYNAMIC ILEUS

is produced by a tonic contraction of the circular muscular fibers of the bowel. This contraction may continue for days. It may be caused by poisoning with lead, tyrotoxin, etc.

MECHANIC ILEUS

or mechanic obstruction: 1, Strangulation of intestine, internal and external (hernia); 2, invagination; 3, obturation, internal (neoplasms, volvulus) and external (incarcerated hernia).

1. By strangulated ileus we mean that not only is the intestinal tract impermeable to its contents, but that the circulation is impeded or suppressed, the nutrition of the coil is shut off and its necrosis is imminent. The mesenteric vessels are the first to yield to the pressure, but the parallel vessel keeps up the blood supply for a long time after, as it is so thoroughly protected against pressure by its position. (Fig. 4 and 5.) In the first variety we have strangulated hernia, inguinal, femoral, umbilical and internal strangulation by diverticula, pseudo ligaments, adherent appendix vermiformis, appendix epiploica, adherent omentum, etc.; strangulations through openings in the omentum and mesentery, retention in peritoneal pockets, or by a twisting of intestine on its axis (volvulus). All of these conditions can produce complete strangulation and necrosis. The danger is great and they run their course rapidly.

2. Invagination holds a middle place between strangulation and obturation, as well for the severity of its symptoms as the tendency to local necrosis and danger to the life of the patient. The symptoms are, as a rule, less pronounced, but of longer duration. Often the invaginated portion may escape necrosis, and should it become necrotic, may slough off and pass through the bowel without causing death. In obturation ileus the symptoms come on slower, the local destruction is more gradual and the danger to life is more distant, depending upon the degree of obstruction and the cause, whether it be simple contraction of the lumen of the bowel, a gradual compression of its caliber by an occlusion from within, an occlusion by a foreign body, as a gall stone, an intestinal fibroma or polypus, a gradual filling and compression from carcinoma or sharp bending of the canal.

Ileus from tonic contraction of the circular muscular fibers of the intestinal wall may produce obstruction with all its concomitant symptoms, lasting for many days.

After this short review of the pathologic conditions we will take up the diagnosis.

Diagnosis.—Can we differentiate with any degree of certainty at the bedside between the various forms of ileus, or between the various groups? This can safely be answered in the affirmative. When we consider that the complexus of symptoms included under the term ileus occurs under so many distinct and different pathologic conditions, it is easily understood why the practice of physicians differs; why the statistics of various men differ; why one class of doctors finds that 100 per cent. of the cases of ileus not operated die, and that another class finds that 34

per cent. of them recover without operation. The reason for these apparent discrepancies is that different pathologic conditions are included under the name of ileus by the various observers.

We will now endeavor to draw attention to the history, the etiology and the clinical course of ileus.

The history will assist us greatly, indeed, if not assure us of a diagnosis of intestinal paralysis following operations on the mesentery, the return of a long strangulated hernia, injuries to the spinal cord, injuries to the afferent nerve supply and strangulated hernia and aids us somewhat in making a diagnosis of thrombosis and embolism of the mesen-

teric vessels. In the reflex paralysis, gall stone colic with or without jaundice, or renal colic, the history of previous attacks aids in the diagnosis. The history is of less value in the inflammatory and mechanical varieties. Here the clinic course, symptoms and signs, will have to be relied upon. The abdominal pain is recognized as a manifestation of irritation of the terminal nerve filaments of the peritoneum, and will vary in intensity, continuity and locality, depending upon the lesion present. Inability to produce bowel movement has already been explained

and may be due to many causes, which will be given in detail in reference to the different groups.

Of the explanations of the mechanism of vomiting, and particularly the fecal vomiting, that have been given, the two most important are the following: 1, that it is due to reversion of peristalsis; 2, that it is due to an overflowing of the accumulations on the proximal side of the obstruction; the increase in quantity is due to decomposition of the contents and transudation from the irritated mucous surface. Schlange has given his support to the latter theory, but it is not the only cause, for in attacks produced by gall stone and renal calculus we have no occlusion of the bowel, nor accumulation on the proximal side to produce an overflowing; still the vomiting is often very persistent, and it is my belief that here a reflex cause is the most potent factor in producing vomiting. Fecal vomiting, when it occurs, always comes from a mechanic obstruction of the intestine, but it has no definite relation to the position or nature of the obstruction. In the literature on the subject we find records of cases where formed feces were vomited. The accurateness of this observation I question. It is a rare occurrence to find material vomited which has the distinct odor of feces. There is an odor different from the fecal, that of decomposition of the intestinal contents which occurs in intestinal obstruction. I have seen but two cases in which a distinct fecal odor was present, and both were obstructions of descending colon. Formed feces could come only from the large intestine, and I believe this has never occurred. The material which has been considered formed feces, is mostly a caseous material, curdled milk which has received its color and odor in the stomach from the regurgitated contents of the intestine.

Meteorismus occurs in three places in the intestine: Above the seat of obstruction, in the occluded loop, or in the paralyzed portion—the latter may be that coil or the entire intestinal tract. The contents of the distended intestine differ materially in the three different conditions. With mechanic occlusion on the proximal side in close proximity to the obstruction the intestine is usually full of liquid feces, principally transudation from the mucosa. With strangulation or occlusion of a coil it is distended about one-third with gas and two-thirds with liquid. The source of this fluid and gas I have demonstrated conclusively by the following experiment to be transudation and decomposition.

Experiment 4.—A dog, weight forty pounds: aseptic laparotomy; six inches of small intestine drawn out, mesenteric vessels supplying six inches of the intestines ligated with silk; segment completely emptied: lumen of bowel closed above and below this portion, precaution being taken to pass the ligature between the muscle wall of the intestine and the parallel vessel, allowing the latter to be free. Examination forty-eight hours after showed the coil very much distended, the wall edematous, slightly discolored over a small area about the size of a nickel on the convex side of the center of the segment. Caliber of bowel about two-thirds full of fluid and one-third gas. This experiment was tried three times, each time with the same result, which demonstrated that the gas was generated within the segment, and that the fluid was a transudate. The same result was obtained, except the quantity of transudation was less when the mesenteric vessels were not ligated, but the intestine itself ligated. Quite another result was obtained when the mesenteric vessels were ligated and the intestine, including the parallel vessel, was closed, as shown by experiment 3.

In the latter experiment after twelve hours there was but a very small quantity of gas and still less

fluid in the coil; it was dark and gangrenous. In less than forty-eight hours with these same ligatures the segment was entirely disintegrated. This shows: 1, that the nutrition of the intestine in strangulation is kept up for a longer time by the parallel vessel; 2, that the gas in the strangulated loop is generated within the coil; 3, that the fluid within the coil does not enter from above nor from below, but is a transudation from the mucous membrane and continues as long as the blood supply from the parallel artery remains, as this artery has no accompanying vein; 4, when the strangulation is rapid and complete, as in Littre hernia, there is no transudation into the coil and but slight generation of gas.

The shape and position of the distended coils will be found to be of great service in making accurate diagnosis of the location of the strangulation. The inability to produce bowel movement is due either to mechanical obstruction or paralysis, the latter may be local, reflex or of central origin. Its phases will be considered in the analysis of the various groups.

Of the constitutional symptoms, one deserving particular attention is the excretion in the urine of phenol and indican. They are the products of absorption of decomposed proteids from the intestinal tract. The indican is present in occlusions of the ileum and absent in obstructions of the large intestine. Albuminuria is very commonly present in intestinal obstruction. In making differential diagnosis the symptoms should be carefully considered in the order of their onset, in the comparative degree of their intensity, the location of their most pronounced manifestations, their continuous or interrupted course, and their relations to physical signs at the various stages of their progress.

Next in importance is a careful physical examination. Inspection, palpation, percussion and auscultation should be practiced systematically in every case of intestinal obstruction, as they have a very positive value in assisting us in making a diagnosis. By these, in intestinal lesions, we recognize the changes in form, in resistance, position and movement of the intestinal coils.

We will now consider the particular forms of ileus.

First. Ileus from paralysis following extensive operations on the mesentery can be at once recognized by the operator and managed better from a prophylactic standpoint than from any other, that is, by a resection of the portion of the bowel where the circulation has been compromised at the time of the operation.

Second. Paralysis from long standing strangulation, I will mention when considering hernia.

Third. Embolism of the mesenteric artery has no pathognomonic train of symptoms or signs, but the history of previous sepsis aids very much in leading to a diagnosis of this rare condition.

Fourth. Paralysis of the intestine from injuries to the spinal cord is readily recognized.

Fifth. Injuries to the afferent nerve supply from direct contusion or from bullet or stab wounds produce ileus where the abdomen has not been involved by the traumatism directly; this variety is usually accompanied by retention of urine, while in perforation of the viscera this symptom is not present. Reflex ileus from renal calculus is recognized by the spasmodic character of the pain, its location in the loin and course of the ureter, its intensity, its reflex

on the bladder and testicle, its duration, the position of tenderness, the progressive change of its location and the information obtained from an examination of the urine. The same symptoms are of value in recognizing periodical hydronephrosis.

In hepatic calculus there is greater difficulty in making a differential diagnosis. First, when the gall stone is still within the gall bladder, the pain gradually increases and reaches its greatest intensity about an hour after the onset; it continues for a few hours and subsides to return again in a short time. It is commonly designated by the doctor and patient as "gastralgia"; the bowels can be moved as a rule within a few hours after the attack begins, and there is always local tenderness in the region of the gall bladder. If a mild cholecystitis be present, there is slight elevation of temperature to $99\frac{1}{2}^{\circ}$ or 100° . The pain often subsides suddenly after a severe effort of vomiting. The patient usually gives a history of having had repeated attacks of the same character. The tenderness remains for two or three days after the attack, depending upon its severity. The following case is a good illustration:

K. P., female, age 32 years. For several years has had several attacks of the following character: First, a sense of fullness and discomfort in the right hypochondriac region; within fifteen or twenty minutes this increased to pain, in one-half an hour the pain was severe and nausea set in. This was succeeded in from thirty to forty minutes by vomiting. If the vomiting was mild the pain would continue; if severe, it would subside. The temperature usually reached 100 degrees; slight tympanites. The patient believing that the attacks were due to biliousness, resorted to cathartics for relief. It always required large and repeated doses to produce an evacuation when pain was present, while under ordinary circumstances a mild cathartic acted freely. Tenderness was present and increased resistance over area of the gall bladder, and when all the symptoms would abate a small tumor could be detected over, but separated from the kidney. Tenderness would increase for three or four days after the attack had subsided, according to its intensity. Albumin in the urine. Patient had never been jaundiced. Diagnosis: Cholelithiasis; impaction of the gall bladder; operation, cholecystostomy; gall bladder enlarged; neck impacted with large gall stones; recovery; cessation of symptoms. The above symptoms contrast markedly with the symptoms of cystic duct impaction, as is illustrated by the following case, which is typical of its kind:

Mrs. Z., aged 36 years, married, six children; excellent health up to 22 years of age. At that time she had a short attack of severe epigastric pain and vomiting. From that time on she had suffered from digestive disturbances and tenderness in the right hypochondriac region. Four years ago she had a similar seizure of longer duration, and during it there was inability to move the bowels. Henceforth the seizures returned every five or six weeks, and for the last five months the pain and tenderness in the hypochondriac region had been constant, with periodic exacerbations. Patient had never been jaundiced. Examination during an attack revealed tenderness in the right hypochondriac region; induration; tympanites, temperature 100 degrees. Diagnosis: Cholelithiasis; impaction of cystic duct. Operation cholecystenterostomy by means of an anastomosis button; gall bladder packed with gall stones; a dozen or more were removed and many allowed to remain; recovery; cessation of symptoms.

When the common duct is obstructed the onset is more sudden, the pain more intense, always accompanied by bile in the urine, often jaundice, depending upon the duration of the obstruction and other symptoms well recognized and familiar to all physicians.

A third variety of reflex ileus is that produced by compression of an ovary, as by fibroids; it may be recognized by the history of the case and the location of the pain, which can be lessened or increased by certain movements of the fibroid and frequently relieved by changing the fibroid from its impacted position.

Dynamic Ileus.—Dynamic ileus or ileus from spasmodic contraction of the muscular wall occurs, first, from ptomaine intoxication, as that obtained from cheese, milk, ice-cream, oysters, etc., and second, from chronic lead poisoning. In the former the pain is intense and often relieved by pressure. The vomiting is incessant; tenderness absent; abdomen retracted; inability to move the bowels; patient collapsed; these symptoms may continue until death, which occurs from toxemia. If the patient survives the immediate effect of the poison, it is usually followed by severe gastro-enteritis.

In making a diagnosis of lead poisoning we have to assist us the occupation of the patient, the history of previous attacks, the blue line of the gums, etc.; but the increased peristalsis, the local meteorismus, the distinct localization of the pain, make it difficult to exclude mechanical obstruction, as the following case illustrates.

Male, aged 40 years; admitted to the Alexian Brothers' Hospital June 10, 1894, and referred to me for operation by the attending physician. Patient gave the following history: Five days previous was attacked with pain of a spasmodic character in the abdomen, followed by vomiting and inability to move the bowels. The abdomen became greatly distended and the symptoms continued up to the time of admission. All efforts to

move the bowels by cathartics, stomach and intestinal irrigation were futile. The physician in charge, who had treated him through a number of attacks of lead colic before, believed this attack differed materially from the others, particularly in its duration, which was five days, and the degree of depression. The physical signs showed the abdomen decidedly tympanitic, and an enlarged coil of intestine could be recognized leading up to the right hypochondriac region, where it suddenly terminated. The patient located the pain at this point. It was decided that a laparotomy would be less dangerous than to allow the patient to remain longer with a possible mechanical obstruction. Median incision; omentum withdrawn, and the hand passed up to the right hypochondriac region, the enlarged coil of intestine was grasped, drawn into the wound; with it came eight inches of a contracted portion, which resembled a solid cord three-eighths of an inch in diameter and was as stiff as a rope of that size. (See Fig. vi.)

At first I believed it to be an organic stricture. The intestine above it measured over two and one-half inches in diameter and was distended with gas and fluid feces. Below, the intestine was empty, soft and pliable. After ten minutes' exposure to the air the spasm at the proximal end began to subside and dilatation gradually advanced to the distal. After twenty minutes the intestine had expanded to about one inch in diameter, was returned and the abdomen closed. The bowels moved within three hours. The patient did not have an unpleasant symptom and left the hospital in ten days. The theory of lead colic advanced, has been that it was due to a tonic contraction of the muscle of the bowel; but from a superficial review of the literature on the subject, I can not find a case recorded

where this theory was verified by observation and examination of the contracted portion as I have noted in this case.

Infection ileus. Ileus from peritonitis occurs under two conditions, namely, that from a circumscribed local inflammation, and from a general peritoneal infection. In ileus from circumscribed inflammation we have the symptoms so commonly observed in circumscribed suppuration at the seat of the appendix. The pain occurs suddenly and may be either local, referred or general, but is most severe at one point. The nausea and vomiting are of short duration, usually not more than one-half hour, and within six or eight hours there is elevation of temperature to 100 degrees, or more, and not infrequently a chill. The information obtained from the pulse is of little significance. Marked resistance of the abdominal muscles and tenderness is present over the seat of inflammation. On the other side of the abdomen the hand can be pressed in without causing pain or inducing resistance. The tympanites is limited. The apparent induration is circumscribed; the deep percussion note is resonant in the early stage. The piano percussion note is flat, and this method of percussion I consider the most important in eliciting dullness when small inflammatory exudates are present. The smallest quantity of fibro-purulent or serous exudate can be outlined by the latter method. Auscultation shows an absence of peristalsis over the region of inflammation, with peristalsis moderately active over the remaining portion of the abdomen. In making a careful examination with the stethoscope and the use of an indelible pencil, it is interesting to note how perfectly the area of adhesion and exudation can be outlined by the absence of peristalsis and subsequently proven in the operation. The symptoms of ileus pass off with these local inflammations in from twenty-four to forty-eight hours, when a free bowel movement can be produced by the use of cathartics. These same symptoms only less pronounced, occur with circumscribed adhesive peritonitis from cholecystitis and tubal infection, and in each case can be differentiated by its location and history.

Note what a great contrast this is to the ileus of general peritonitis. In this variety the pain is intense and extends all over the abdomen; the nausea and vomiting are persistent for days; the temperature elevated to above 100 degrees except in the presence of collapse; the pulse frequent, small and thready; the skin cold; the countenance depressed; anxious expression; enormous and uniform meteorismus; absence of respiratory movements in the abdomen; knees flexed. On palpation resistance is greatest over seat of origin; muscles are firmly contracted; deep percussion note uniformly resonant; piano percussion note dull over area of adhesion and exudation; complete absence of peristalsis. An uniform splashing sound with each respiration, caused by motion of fluid in bowel must not be mistaken for peristalsis. In this the sound is uniform with every respiration; in peristalsis it varies constantly. It is impossible to induce a bowel movement; the obstruction is as complete as if the intestines were ligated, and remain so until a few hours before death, when relaxation takes place. To the inexperienced this is considered an indication of relief of the "obstruction," but it is really a sign of impending dissolution. The cause of the ileus in these cases is a peripheral paralysis.

What should our treatment be in cases of ileus from circumscribed and general peritonitis? It should be immediate laparotomy. By this means in cases of circumscribed peritonitis the cause may be eliminated and the inflammation prevented from becoming general, not that all cases would die immediately as a result of the disease, but that the immediate and remote dangers without operation are very much greater than with operation. In general peritonitis the danger is great both with and without operation, but it is my firm conviction that an early operation, that is an operation within twelve or twenty-four hours after the onset of the symptoms, will save a large percentage of the cases. An operation in the late stage, when the patient has cold extremities, is pulseless at the wrist and dissolution is imminent, should be discouraged, as it does no good for the patient and brings discredit on surgery. The importance of early operation in general peritonitis is illustrated in the two following cases:

Case 1. Referred to me by Dr. James G. Berry. G. F., aged 19, weight 220 pounds. On the morning of Sept. 8, after breakfast, he was attacked with severe pain in the abdomen. This was shortly followed by vomiting. The pain and discomfort were sufficient to compel the patient to remain in the house, but not in bed. On the following morning at 10 o'clock, twenty-six hours after the onset of pain, he walked a couple of blocks and consulted a druggist as to his condition. He was advised to see a doctor. About 3 o'clock he was seen by Dr. Berry, when a diagnosis of appendicitis was made. At 4 o'clock his condition was as follows: Pulse 140; temperature 102°; tympanites excessive; tenderness most marked on deep pressure over appendix; peristalsis absent; inability to produce bowel movement; patient's facial expression good. He expressed himself as feeling tolerably comfortable. Respiratory movements of the abdomen absent; deep percussion note resonant; superficial dullness over the entire abdomen. Immediate laparotomy. The abdomen was opened two inches to the right of the median line parallel to the external border of the rectus. On opening the peritoneum, a sero-purulent fluid escaped. There were no adhesions. Pus was found in all directions, a large quantity of it being in the pelvis. The cause of the peritonitis was found to be a pressure atrophy of the appendix with perforation. There were no adhesions around the appendix; no gangrene of the mucous membrane. The peritonitis was produced by a direct perforation of the appendix from pressure from a calculus. The pus was sponged out, drainage glass tube and gauze. Normal gloss of the intestine was not disturbed in the least by the presence of pus; the surface was not even red. The patient made an uninterrupted recovery.

Case 2. Referred to me by Dr. D. R. Connell, Oct. 21, 1894. B. P., female, aged 21. Ten o'clock on the night of Oct. 20, the patient experienced severe pain in the abdomen, followed by nausea and vomiting, great tenderness and a temperature of 100.6 degrees. Diagnosis appendicitis. Operation thirty-six hours after the onset of symptoms. At the time of operation the abdomen was uniformly distended and tender, absence of peristalsis, inability to produce bowel movement, patient still vomiting, pulse 120, and temperature 100.5 degrees. Deep percussion note resonant; superficial (piano) percussion note on the lower part of abdomen dull, on the upper resonant. Celiotomy. No adhesions of peritoneum; the coils of intestine in all directions were covered with pus. Half a pint of pus was found in the cul-du-sac of Douglas. Intestines not eroded, slightly congested, still glistening; appendix adherent; a few flakes of lymph on its surface; an ulcer of the mucous membrane, but no perforation present. The source of infection was evidently the appendix, infection traveling through the wall at the seat of the ulcer or by the lymphatics. The pus was sponged out, no irrigation, glass and gauze drains in all directions. Rapid recovery.

The result in these two cases shows what can be accomplished in early operation for suppurative peritonitis; but this favorable outcome must not be expected from the dry, ecchymotic, excoriated peritonitis from streptococcus infection.

Cases of adynamic ileus have only recently been brought to the attention of the surgeon, but from the

illustrations of the varieties given it will be seen that there is a fertile field for intelligent surgical interference, based on accurate diagnosis.

(To be continued.)

PRIVATE DISPOSAL OF HOUSEHOLD GARBAGE.

BY D. H. GALLOWAY, PH.G., M.D.

CHICAGO.

One of the first problems which engaged my attention on taking charge of Dr. Bayard Holmes' Private Hospital, was the disposal of hospital and kitchen refuse.

It was imperative that soiled dressings should not be put with other garbage to be hauled about the city and be handled by many persons. Even throwing them into a metallic vessel, to be carried from room to room and to be handled at least once more when the vessel was to be emptied, was repugnant to me. That ever-present article—at once a nuisance and of unlimited usefulness—the old newspaper, seemed to be "indicated."

When a soiled dressing was removed from a wound it is was immediately rolled up in a newspaper and put into a receptacle provided for the purpose. When the morning dressings were all done these small packages were made into large ones with more paper, and in this way conveyed to the furnace room. All repulsiveness and danger were thus obviated. This led me to contrive a way to dispose of all hospital and household refuse which has been in use in this hospital, with perfect satisfaction ever since. It is simple, inexpensive and effective.

I require that all garbage of whatever kind be wrapped into packages with newspaper or other paper as the butcher wraps up a steak. Tin cans and other non-combustible material, of course, not included. A wire basket drains as dry as possible all garbage containing water. When the furnace is not in use it is prepared by closing all registers as well as dampers in hot air pipes, and opening all drafts. A small amount of kindling is put in the furnace and on this the packages are piled. When the furnace is full the kindling is ignited and it is left to itself. Next day the furnace will be found empty except for a small quantity of fine ashes. Even melon, lemon and orange rinds, cobs and husks of green corn, potato parings, coffee grounds, etc., are completely disposed of in this way. Sometimes I have found it necessary to light a newspaper on top of the garbage in order to start a draft up the chimney, but ordinarily there is no trouble, little heat, no odor and no smoke is noticed about the building. This applies to the summer when the furnace is not in use. I found it a little more difficult in winter, and once I thought I should be obliged to give it up. After some trials, however, I found the following method entirely satisfactory. In the morning all drafts are opened, the fire is shaken down and fresh coal put on, then the packages of garbage are put in on top of the coal. After ten or fifteen minutes the drafts are arranged as they would be if no garbage had been put in, and the next time the furnace needs attention the garbage has disappeared. After putting the packages in the furnace they should never be broken up or stirred with a poker. At first sight it would seem that a considerable amount of fuel would be required, but such is not the case. Our family consists of

from twelve to twenty persons, and such a family will make a large amount of garbage each week; yet during the entire summer I did not use altogether a dollar's worth of kindling. Fruit baskets, berry boxes and other readily combustible material furnished most of the fuel necessary.

This method has been in use in this hospital for more than a year, and in that time absolutely not a pound of garbage has been put into the street, nothing but ashes, tin cans, broken glass and crockery. The secret is in the packages. The difference between these and loose garbage in the matter of combustibility is the same as the difference between lump coal and slack coal, the one will burn where the other will extinguish a fire. How to dispose of the garbage of cities is one of the most vexing of the great economic problems of this age. Burning is a wasteful process and dumping into lakes or water courses is disgusting and at all times a menace to the health of the community. All refuse organic matter, whether animal or vegetable, should be returned in some form to the soil as fertilizer. It is a mine of wealth wantonly wasted. If given an opportunity nature's laboratory would transform the nauseous stuff and return it to us in fruits and flowers and a thousand other attractive forms. The present method of disposing of this vast portion of nature's labor is a heavy draft on our inheritance which must sooner or later be stopped; unless the chemist realizes his dream of making animal food in the laboratory direct from the inorganic world.

If, however, it must be destroyed, it should be by fire and not by being piled up in great dumps to breed disease, nor thrown into water where it may be conveyed to great distances spreading pestilence by the way. If it is to be burned, then the nearer the source of supply—the household—the less offense and expense will it cause. It is produced in greater or less quantity by every family, but how few exercise any care about its disposal. It is carried into the street or alley, thrown into a wooden box and then left to stew and rot and stink until the scavenger comes along and gathers it up. Even then the offense is not removed for the box continues to emit foul odors and is a culture ground for all sorts of disease-producing germs. Waste paper is one kind of garbage which every one ought to be able to dispose of without throwing it into the street. Yet I have literally seen hundreds of newspapers and pieces of wrapping paper from dry goods stores, groceries, and meat markets, the last covered with grease and flies, piled about a large flat-building so that if one had set fire to the rubbish it would have seriously menaced the building. The tenants in such buildings, using steam heat and gas ranges, have no facilities for burning even waste paper, but there is always a furnace in the basement and provision should be made for conveying to the furnace and there burning it. Many of the tenants of these large buildings make a practice of throwing all waste paper out of the windows. This practice is an offense to the rest of the community and should not be tolerated. A few arrests with a nominal fine of a dollar and costs, and due notice of such arrest and fine in the daily papers, would greatly stimulate a healthy public sentiment against the practice of throwing rubbish into the street.

One very windy day I saw a woman sweep out of a vacated store enough waste paper to make a good-

sized wagon load, and this paper littered the street for a mile in the time it took me to ride that distance on a bicycle.

A most provoking, because unnecessary, nuisance is the rubbish brought by the wind and deposited in dooryards and passageways. Every householder who has any regard for the appearance of his lawns must gather up this litter two or three times a day, and only the person who gathers it up can form any conception of its great quantity. The man who deliberately throws upon the street something which he knows another must go straightway and pick up, exhibits a selfish disregard of the rights of others which is evidence of moral degeneration or arrested development. There is one other thing to which I wish to call attention. Horses are driven about the streets dropping filth which is dried in the sun, powdered by passing vehicles and blown by the wind into our mouths and nostrils, onto our tables and into our food. Why not require that every horse carry, attached to its harness, a receptacle into which the dung would fall? Such a thing could be of leather and not overly conspicuous. Would this not be cheaper, to say nothing of the other considerations than to hire an army of men to go about and gather it up? No doubt this will bring an incredulous smile to the face of many a reader. People are prone to submit to anything, no matter how disgusting or dangerous, if it is time-honored. There is a feeling that because an evil *has not* been corrected it *can not* be corrected. A few years ago the bicycle was considered an interloper upon the streets which were held sacred to the horse. In a few more years I expect to see the tables turned by the bicycle and other machines for locomotion and transportation, and then the man who drives a horse will be compelled to take some such precautions as mentioned or be confined to certain streets or alleys.

26 39th Street.

CEREBRAL LOCALIZATION IN THE LIGHT OF RECENT HISTOLOGIC RESEARCHES.

BY CHARLES K. MILLS, M.D.

PHILADELPHIA.

A year or two ago, we were inclined to think that the subject of cerebral localization had been practically settled, and that we were not likely to get much new light upon mooted questions.

Recent histologic investigations—brought together in a valuable paper in *Brain*, by Andriezen, which paper also contains much original work—have divided and subdivided the cortex into new layers and sublayers, and have determined and traced the constituents of these layers in a manner which a few years ago would have seemed utterly impossible. The resulting generally accepted histologic subdivision of the cortex is into four layers—the molecular ambiguous, great pyramidal and polymorphic. The molecular layer, which is the most superficial cortical strip, has been subdivided into strata, and more than a dozen cell and fiber systems have been traced to it and within it. Practically, the standpoint which I have always taken with reference to the question of sensory and motor localization, is that which is still held by Bechterew, Ferrier and others; namely, that just as we have separate auditory, visual, gustatory, olfactory and motor zones, so we have

a separate cortical localization for what is sometimes termed common sensibility; in other words, for the representation of such cutaneous and muscular sensations as touch, pain, temperature, pressure, and the location of a limb or part.

According to Andriezen, the terminals and collaterals of the main portion of the fillet radiations, that portion which conveys cutaneous and muscular sensory excitations, pass into one of the strata of the molecular layer, of the Rolandic as of other portions of the cortex, to there come into contact with the apical processes of the great pyramidal and ambiguous cells. Andriezen would therefore call these cells the first sensory cells of the cortex, no matter where they are situated. This view might therefore be regarded as making a sensori-motor region of the area around the central fissure; or rather, if carried to its logical extreme, as making the entire cortex simply a region for the reception of sensory impressions.

For the practical purposes of the physician and surgeon, no matter what view may be taken of the nature of the processes going on in the cortex, it would seem best to still hold to the view of the separate localization of areas for the special senses, for motion, and even for muscular and cutaneous sensibility. Lesions of these areas produce phenomena of vision, audition, motion, sensation, etc., which are not produced when the lesions are situated outside of the special areas to which the functions above mentioned are assigned. The fillet radiations for cutaneous and muscular excitations, as a compact bundle, probably reach or most closely approach, the outer layer of the cortex in the postero-parietal convolutions and in the limbic lobe. Whether we should regard the cells and fibers which bring about communication between these regions and the motor cortex as true sensory terminals or as simply constituting a field of conjunction, the only cortical and subcortical lesions which will produce pure and marked sensory symptoms will be those occurring in these areas. "These incoming messages," says Andriezen, "which inform the brain of the movement of the limb, arrive (strictly speaking) not in the pre-Rolandic but in the post-Rolandic (ascending parietal) convolutions. In the pre-Rolandic or ascending frontal convolution, and in the adjoining posterior portions of the three frontal convolutions as well as the prolongation of these areas on the mesial (marginal) convolution, we find the last term in the cortical series, the finally disposed executive mechanisms."

It would perhaps be best to define the cortical area for cutaneous and muscular sensations, as that part of the cerebrum where the fillet radiations most nearly approach the surface of the brain, before their final ramifications in the molecular layer, still holding to the old view with reference to the motor cortex. Andriezen, as already stated, speaks of the pyramidal and ambiguous cells as the first sensory cells of the cortex, because the terminals of the fillet radiations or their extensions, first touch the apical processes of these cells, and therefore these cells first receive sensory impressions from the periphery of the body. It would be better, following Forel and Nansen, to disregard entirely the subdivision into the cells of sensation and motion, and take the broad ground that we are simply dealing with the greatest and highest of sensori-motor areas, and that in the region posterior to the area usually recognized as motor, the last stage in the sensory process is reached,

while in the Rolandic cortex the first stage in the motor portion of the process begins.

DISCUSSION.

DR. J. F. BURNISHED, of Long Island City, New York—The subject brought up by Dr. Mills is of great importance, not only to the specialists in nervous diseases, but also to the general practitioners, to which latter class I belong. I have had some twelve cases of trephining to do and I know what puzzling conditions will beset a man in regard to cerebral localization. Any studies which will throw more light upon this subject will be eagerly availed of by the general practitioner.

THE ETIOLOGY OF TINNITUS AURIUM.

Read before the Society of Ophthalmology and Otology of Washington City, Oct. 8, 1895.

BY S. O. RICHEY, M.D.

WASHINGTON, D. C.

Impaired hearing and tinnitus aurium are the two most common and distressing subjective symptoms of affections of the ear for which our aid is sought. Often the individual has reconciled himself to the impaired hearing, but is urgent for relief from the persistent torturing sounds of which he has the monopoly. The character of the tinnitus exciting most complaint is the ringing, buzzing, twittering, ticking or grating sound, which is as constant as the chronic progressive deafness with which it is associated, varying only in power or intensity at different times.

Of the many causes of tinnitus aurium a number are promptly recognized, and have only to be understood to be relieved, viz., small objects on the drum membrane, or in the external meatus; obstruction of the Eustachian tube, or of the external auditory meatus; overdoses of quinia or of the salicylates; the use of tobacco or alcohol in some persons; worms, fluid in the tympanic cavity, polypi and tumors of the cervical region; in none of which is the tinnitus of the distinctive character above described.

The cause of tinnitus is not always so apparent, nor when discovered so tractable to our efforts for its relief; as in hyperemia and anemia of the brain and the deeper structures of the ear; from the menopause or menstrual irregularities; from nervous shock, hysteria, mental excitement, worry or over-fatigue; from concussions and from morbid conditions of the heart, liver or kidneys. Ankylosis of the ossicula auditus, especially of the foot-plate of the stapes in the foramen ovale, is an active factor in the etiology of tinnitus. Ankylosis of the other articulations, while difficult to relieve, does not offer the formidable embarrassment which attends ankylosis of the foot-plate of the stapes, because they can be reached through the Eustachian tube by means of vapor of iodine and the joints rendered movable by this means and by the *tapotement* inseparable from inflation of the tympanum. They are cases which may be, and are, relieved by such treatment; those which are not so influenced will be found to depend upon ankylosis of the stapes in the oval window.

The operation of excision of the drum membrane with the incus and malleus does not reach the seat of the trouble, and in the instances in which tinnitus has been relieved by it (as in the case of Burnett, of Philadelphia), the ankylosis of the foot-plate of the stapes, being yet very slight, was unintentionally disturbed by inadvertent manipulation, in separating the incus from the stapes. Such relief must necessarily be temporary, as the ankylosis will recur.

To repeat, if the tinnitus be due to ankylosis of the malleo-incudal or the incudo-stapedal articulations, it may be relieved by proper manipulation short of excision.

Stapedectomy was promising, but the results were disappointing, owing to the fact that instead of detaching the stapes in its entirety, the crura were usually broken off, leaving the foot-plate still engaged, for in the affection considered, the crura become very brittle. Even if the foot-plate had always been removed with entire relief, the improved condition could not last, unless such treatment were adopted as would stay the further progress of the cause, which has been shown by Politzer¹ to be a "circumscribed primary affection of the labyrinthine capsule, exhibiting, post-mortem, in the region of the niche of the oval window, more or less sharp bony protuberances, covered mostly with normal mucosa, the neoplastic bony tissue gradually pushing aside the normal bone and attacking the oval window and stapes, producing ankylosis of the stapes. The round window may also be very much contracted."

The sixteen cases dissected, after a history which offered the clinical symptoms and usual course of what is called chronic dry catarrh of the middle ear, show that the foundation of the deafness and tinnitus is not in the mucosa at all, but is referable to a neoplastic hyperostosis of the bony envelope of the labyrinth. The development of the deafness dated mostly from many years back. Occasional sensations of pricking or tearing pain within the ear were complained of, but the chief characteristic was the constant and vehement tinnitus.

Two of the cases described suffered from gout; if syphilis was present it could not be determined; heredity, gout and syphilis are the suggested possible etiologic factors. The paper regards cure as nearly hopeless, but the internal use of iodine may prevent a too rapid advance of the disease. Dr. Politzer's communication seems to me the most important that has ever been made on this subject, and fully explains the failure of stapedectomy; in over twenty cases reported of this operation by Blake, of Boston, he found bony ankylosis at the oval window, which rendered the stapes immovable and prevented its complete removal in more than half the cases. If the operations had been successful, in order to make the result lasting, other means would be necessary, which adopted in time would make such an operation unnecessary; such means as would put an end to the disease process.

Stapedectomy is not without risk, because, by entire removal of the stapes an open channel is left between the tympanic cavity and the labyrinth, which is by nature placed securely beyond the reach of external noxious influences. Rationally, this ready access to the labyrinth must be a source of danger. In what way mischief would develop can only be surmised, as none seems to have been observed in the cases so far operated upon, because probably of the careful asepsis observed.

That loosening an ankylosed stapedial base-plate will improve hearing and relieve tinnitus beyond help in any other way, would seem to have been shown by an accident to one of my patients two years ago.

The wife of a western Senator, 35 years of age,

¹ Knapp's Archives of Otology, vol. XXIII, p. 255.

with progressive deafness, had improved under treatment, but became impatient of restriction and violated continuously the line of conduct prescribed for her. Her trouble increased upon her rapidly. About two years ago she was thrown from her carriage and "something snapped very loud; she heard at once very well." She came to me to say that the accident had cured her, when I could not do so. By persistently questioning me she secured the information that the comfortable effect was only temporary, that she was *not cured*. In a few months she was in much the condition previous to the accident. She had been thrown upon her head and an imperfectly ankylosed stapedial foot-plate was loosened by the jar. Why should a much more lasting effect be expected from a perfect stapedectomy?

Professor Politzer's view that iodine promises the least possible effect in such cases, accords with my clinical experience. It may be remembered that I asserted some years ago (*American Journal of the Medical Sciences*, April, 1887,) that the local use of iodine helped some persons; that it was my chief reliance in such cases. Among the causes of intracranial circulatory disturbances, one of the factors in the causation of tinnitus, have been named morbid conditions of the heart, liver or kidneys. It is not possible to separate such conditions from what Politzer considers a cause of the hyperostosis, gout. A paper by the writer, read at the Ninth International Congress, discusses the affection as related to arthritis deformans, a form of gout, and says: "Iodine vapor is our sheet anchor for topical application," aided by clothing, food and other items of general treatment, among which "the salicylates have had manifest influence in some cases;" the failures were supposed to be "osseous ankylosis, or disarticulation of the ossicula." This view, as Politzer's observations do, includes all causes of intracranial circulatory disturbances, except concussion, and materially simplifies the question.

Finally, as to the effect of treatment in these intractable cases, the cause of which is not superficial or easily removed. Until lately the constitutional exhibition of iodine has received no attention from me (why, I do not know), for good, if not sustained, results from its local use alone has been my experience. It is now being used, both locally and constitutionally, in a number of cases in which it had been used locally with favorable influence. The local use is continued, because it appears to determine to this region the effect of what is given by the stomach, and because, in my experience, its topical influence has nearly always been good. If the gouty materies morbi is responsible for the affection, as we have reason to believe, then diet, baths and clothing must enter into its management. And beside iodine, other drugs have a useful purpose; to name them and particularize their effect would require too much space for present consideration.

In 1886 a young woman, manifestly gouty, presented herself for relief of impaired hearing and distressing tinnitus. "The men and women of her mother's family, of her mother's generation, are all as deaf as posts." My watch, which can be heard at twelve feet by a normal ear, was heard at ten feet by her right ear; at one inch by her left ear. Accumulated cerumen being removed from the left meatus, hearing of the left ear was increased to ten feet. Accumulated cerumen being always due to some

deep-seated affection, I advised that her ears be treated, but a few months later she went abroad, and I did not see her again until 1893, when, with the watch, the hearing distance of the right ear=10 inches; of the left=13 inches. There was no further accumulation of cerumen. Subjected to local and constitutional treatment March, 1895, W.H.D.D.A.=14 inches, S. A.=58 inches.

In all this time the tinnitus entirely ceased only for a short period to recur after a runaway accident, in which she was violently thrown to the ground; again, for about two weeks, while she was at the springs taking the baths. The hearing for the same watch now is, D. A.=26 inches; S. A.=10 feet. The improvement for the voice has been such that she has little difficulty in ordinary conversation. When last tested, though the windows were down, she was confused by the chirping of park sparrows in the yard. Her tinnitus varies.

A man, 50 years of age, whose tinnitus has been constant and unvarying; whose deafness was such that conversation had to be specially directed to him in a loud voice from two or three feet distant; whose record for other tests I have not at hand, and who has paid me an occasional visit for ten years past, has improved so much under the additional treatment for three months that he informed me at our last interview that he had attended "a board meeting," and heard what passed with little difficulty, and that his tinnitus had ceased for twelve hours after his previous visit.

It is my hope to make a report of interest on this subject at some future time.

SOME OF OUR LATE THERAPEUTIC RESOURCES.

Read at the Northern Tri-State Medical Association, at Toledo, Ohio, Dec. 10, 1895.

BY J. F. JENKINS, M.D.
TECUMSEH, MICH.

Within the past score of years there has been a new light thrown upon a large class of maladies which bear the name of contagious diseases. Plausible theories relative to the cause of many of them have given way to demonstrated facts. The consequence is that different methods of treatment have been adopted for the relief and cure of many of them. Modifying and attenuating the poison which produces the disease is a method originally wrought out by Pasteur, first in securing immunity in fowls against chicken cholera and lastly in the prevention of hydrophobia; and still it is a problem whose solution is engaging the attention of some of the best minds in the profession, which when completely solved will doubtless lessen the death rate of that class of diseases which has heretofore been the scourge of the human race in every quarter of the globe. Probably the most sanguine minds of the present day do not for a moment entertain the idea that contagious diseases will be completely eradicated in the future by the discovery of more potent therapeutic means, but we have every reason to believe that the death rate will be greatly reduced by better therapeutic agents, together with a more efficient code of sanitary laws, international in character, embracing every civilized country in the world; then the great epidemics of the past will never be repeated in the future.

Koch, proceeding along the same line of investiga-

tion that had been previously laid down by Pasteur prepared from a cultured medium in which the tubercle bacilli had been grown, a preparation which he designated tuberculin. This remedy, of which so much was expected as a specific for tuberculosis in its various manifestations, has proved a failure as a specific, but in the hands of a few physicians it is used in properly selected cases, and by them with satisfactory results. Dr. Karl Von Ruck, of Asheville, N. C., uses tuberculin in minute and what he terms safe doses, but so far as the writer's observation goes, he does not define the amount given. Although tuberculin has not met the expectation of the profession in the treatment of tuberculosis, yet in the field of veterinary surgery it is a remedy of the utmost importance in the diagnosis of tuberculosis among cattle, and for this purpose it undoubtedly has its largest sphere of usefulness.

Prof. Klebs has separated a substance from tuberculin which he terms antiphthisin, which is claimed by him to represent the curative, minus the poisonous properties of tuberculin. It is administered by Prof. Klebs, Dr. von Ruck and others in the early stage of tuberculosis before the tissues become broken down. Klebs states that its curative properties are due to its germicidal action on the tubercle bacilli. The report of tubercular cases treated by these gentlemen in which antiphthisin was the agent are interesting and instructive. Within the past year serum therapy has been brought to the notice of the profession by Prof. Maragliano, of Genoa, and Dr. Paul Paquin, of St. Louis. This remedy is undergoing investigation by the originators and a number of others are in the same field of research. Whether or not, future treatment of pulmonary tuberculosis by serum therapy will prove its utility is a problem yet unsolved.

Prof. Vaughan has been investigating the therapeutic properties of yeast-nuclein and finds that when this preparation is introduced into the system, that it has a decided germicidal action. The clinical report of cases which Dr. Vaughan has already published indicates that the remedy has a marked curative effect in the treatment of tuberculosis.

Dr. Vaughan makes the following statement in a recent communication to the writer: "I have not gone over all my cases, and consequently can give you only partial information. I have treated with nuclein forty cases in the second and third stages of the disease. Of these, twelve have apparently been greatly benefitted. All of these twelve have gained in weight and in some five of them the germ has at least temporarily disappeared. I have treated twenty-seven cases without cavities and all of these, with one exception, have been apparently markedly benefited. In a large majority of these cases the germ has disappeared from the sputum. I have treated five cases of tuberculosis of the urinary organs; four of these have apparently been cured. The fifth was temporarily benefited, but later the disease extended to other organs and the patient must soon die."

The most important remedial agent which has been brought to notice in the last decade is diphtheria antitoxin. Through the researches of Behring and Roux definite principles have been established for the treatment of diphtheria by serum therapy. The remedy has been criticised by many of the leading men in Germany, France, England and our own country. Notwithstanding doubts relative to the

beneficial effects of antitoxin in diphtheria, it has been very largely administered in the hospitals of Europe and America. When an early diagnosis of diphtheria is made and the antitoxin treatment adopted within the first twenty-four or forty-eight hours of the attack, the result appears to be more satisfactory than when prescribed later in the disease; yet throughout the disease, both local and general treatment is recommended. No grave complications have been reported resulting from the remedy, although occasionally a troublesome urticaria takes place, which usually disappears in a few days. No renal or heart complications have been reported following the use of antitoxin, so far as the writer has observed. Recent statistics from German hospitals and private practice show that of 10,240 cases of diphtheria, in which 5,790 were treated by antitoxin, 4,450 were treated by other methods; the death rate in the former were 9.4 per cent. In the latter 14.7 per cent., and in cases where antitoxin was given within forty-eight hours of the attack, the death rate was only 4.2 per cent. In a communication lately received from Dr. Hermann M. Biggs, Bacteriologist to the Health Department of the City of New York, he makes the following statement relative to the death rate from diphtheria:

"The death rate in New York has decreased about 40 per cent. since the use of diphtheria antitoxin."

Dr. Welch, of Johns Hopkins Hospital, states that the study of the results of the treatment of over seven thousand cases of diphtheria by antitoxin demonstrates beyond all reasonable doubt that antiphtheric serum is a specific curative agent for diphtheria surpassing in efficacy all other known methods of treatment for the disease. It is the duty of the physician to use it.

Antitoxin will not cure every case of diphtheria, even if administered in the first twenty-four hours, but the consensus of opinion undoubtedly is, among those who have the largest clinical experience with the remedy, that its beneficial effects in the treatment of diphtheria is unquestionable. The dose of antitoxin is from 500 to 1,500 units, Behring's standard, or from 5 to 15 c.c. The dose will vary according to the age of the patient and the intensity of the disease. Under similar conditions it will require from 1,000 to 4,000 units in the treatment of a case of diphtheria. The syringe for injecting the serum should hold about 15 c.c.; the needle as well as the skin should be aseptic and the injection made in the subcutaneous cellular tissues, over the pectorals, or in the buttocks. From 100 to 400 units of antitoxin injected in a person, it has been observed, will give immunity from diphtheria for the period of four weeks.

From the history of reported cases the temperature falls in the course of twenty-four hours after the injection in mild cases, while in the more malignant it slowly falls after the second or third injection. The pulse rate is lessened, but not in proportion to the fall of the temperature. After the first injection in the majority of cases the false membrane ceases to spread and in forty-eight hours, as a rule, it becomes detached. Tracheotomy is less frequently demanded and intubation, when necessary, will seldom be required longer than twenty-four hours. Albuminuria is not so frequently observed and appears milder in character. The above conditions doubtless hold good in the majority of cases treated by

diphtheria antitoxin, of which there are many exceptions.

Brown-Séquard introduced glandular extract in the treatment of disease. Within the past few years Dr. George Murray, of Newcastle-on-Tyne, has brought before the medical world the treatment of myxedema and its twin sister cretinism by the extract of the thyroid gland. The reported cases of myxedema in which the thyroid extract has been prescribed conclusively prove the beneficial effects of this remedy in a disease which has hitherto baffled all remedial agents. Several theories relative to the etiology of Addison's disease have their adherents. The latest and probably the correct one is the toxic theory. Prof. Schafer and Mr. Oliver have made a number of experiments on dogs and guinea pigs with the extract of the suprarenal capsule, and from these experiments we are led to believe that the future and successful treatment of this intractable disease will be the extract of the suprarenal capsules.

The clinical history of a case of Addison's disease has been recently reported by Dr. Stockton, of Buffalo, in the *Medical News* (Nov. 16). The uncooked adrenals of a sheep were prescribed, of which the patient took in the form of sandwiches from one to two a day and sometimes three a day were taken without any unpleasant result. Five gallons of oxygen were inhaled three times a day. The health of the patient has gradually improved, which, in the opinion of Dr. Stockton, is due to eating the adrenals of the sheep.

A SAFE AND SURE METHOD OF REDUCING ENLARGED TONSILS.

BY H. W. KENDALL, M.D.

QUINCY, ILL.

The etiology of acute and chronic tonsillitis seems settled in the minds of all pathologists, but my experience points to a cause entirely overlooked by all the authors that I have consulted. Super-acidity of the *prima viæ* is in my opinion the essential cause of both the acute and the chronic disease, the catarrhal accidents being merely exciters.

I think that in every case of acute or chronic inflammation of these glands the salivary secretions will be found acid instead of alkaline, and that free doses of potassium or soda locally applied and ingested will give most rapid relief. The anatomy of the tonsil is well understood, but the great variation in the size and number of excretory ducts has not been particularly pointed out. These ducts are greatly enlarged in either acute or chronic hypertrophy of the glandular structure unless contracted by astringent or caustic applications. Since the general disuse of astringent gargles, suppurative cases are rarely seen. Cauterization, once the general practice, is now almost abandoned for the reason that it is obstructive and converts the acute into the chronic condition.

We have an efficient cauterant and at the same time an antiseptic and alterant in pure hydrochloric acid, which is always friendly to human flesh. This is the agent that I have found so efficient in reducing enlarged glands in all parts of the body, but the method of using it is the particular point that I wish to present in this short paper. My method is the use of capillary glass tubes (Bohemian or Whital and Tatum's glass), one-eighth of an inch caliber, heated in a Bunsen flame and drawn to a point, the shaft of

the drawn part two inches long with caliber one sixty-fourth of an inch, broken off and fire polished. Now if the shaft of the tube is five inches long the drawn part will hold, after dipping in a fluid, one minim; if the larger shaft is increased in length it will hold more. When the point of this tube touches any substance it will deposit a fraction of the drop; by long contact it will deposit all that it contained.

I dip these tubes into pure fuming hydrochloric acid and push them into the excretory ducts of the tonsils, three in each gland at each sitting, twice a week. This operation is painless and produces no inflammation or swelling. Five or six applications are sufficient for moderately enlarged glands. Nitric acid used in the same way will produce swelling and sloughing. Chromic acid so used is rapidly effective, but I abandoned it forever after producing tetanus in a malignant case.

The advantages of this mode of application are the ability to deposite a definite and minute amount of acid and avoidance of strangulation and choking effects of the fumes. After ten years' experience with this treatment I can quite positively say that in my opinion tonsils ought never to be removed with knife or scissors. By careful, gentle and rapid manipulation of the first application any child will submit to the treatment willingly.

If a local anesthetic is desired a saturated solution of bromid of potassium and bicarbonate of soda is better than cocain because the latter produces subsequent delirium or dizziness with asthmatic breathing in many cases.

DACRYOCYSTITIS.

Read before the Falls City Medical Society.

BY P. RICHARD TAYLOR, M.D.

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS AND DEAN OF THE HOSPITAL COLLEGE,
LOUISVILLE, KY.

Dacryocystitis is an inflammation of the lachrymal sac, generally accompanied by a catarrhal condition of the entire lachrymal passage. The disease seldom, if ever, originates in the sac, but is a complication of trouble in the nasal passage induced by obstruction of the lower opening of the duct, or inflammation of the nasal membrane, or periostitis. These are the principal causes, and almost invariably originate below and extend upward to the sac. Inflammatory conditions of the conjunctival sac rarely produce dacryocystitis.

The disease is easily diagnosed by tenderness and swelling over the sac with edema extending to the lids, swollen caruncle with epiphoria, and puncta swollen to twice the usual size. This condition always develops stricture which, as a rule, is situated below the sac, except in those cases where the duct is obstructed at its lower opening by deformity of the turbinated bones closing in the nasal end of duct. Removal of the turbinated bone will allow the sac to empty its contents.

When dacryocystitis has once developed and pus has formed, a stricture will certainly result. The pus can be evacuated with little difficulty by making firm pressure with the finger from above or below, forcing the pus from the sac into the eye or into the nasal cavity. But the evacuation of the pus is not our sole object. Our chief aim is to get rid of the stricture.

We have the sounds and probes, blunt and bulb

pointed, with which, after slitting the puncta, we are enabled to dilate the offending stricture. Experience with these instruments has taught us that dilatation of the stricture does not cause its complete absorption, since a simple *coryza* may produce a recurrence of the trouble. We might cut the stricture and continue the dilatation with probes. It is an easy matter to evacuate the pus, to daily probe and wash the passage until it is seemingly well. Yet it will be certain to recur unless the probing is continued until the stricture is absorbed, which is seldom, if ever, accomplished by this method. The radical cure depends on keeping the passage open with free drainage, which can only be accomplished with a tube.

Some authorities recommend a lead wire with one end in the nasal cavity and the other projecting and bent downward at the inner canthus, and worn until the stricture is absorbed.

Since probing is a failure, when one of these cases falls into my hands I always split the punctum, and, with a probe-pointed bistoury or a spear-pointed knife with a malleable shank, cut the stricture. Recently, I have been using a double-edged Graefe's cataract knife. It is passed through the passage into the nose and the stricture is cut in several places by turning the knife before withdrawing it. I cleanse the tract with an antiseptic solution and put in a lachrymal tube at once. The passage can be washed while the tube is in position. Epiphoria can only be relieved by a tube which will perfectly drain the conjunctival sac. All lachrymal tubes are made on the same general plan, but the one which I have devised and which I now show you is somewhat different. It meets the requirements more fully than any I have yet used.

This tube is seven-eighths of an inch long and three-eighths inch angle, and can be made any size and of any metal. It differs from all others in having a lateral slit on both sides of the short end, leaving a duck bill spout with upper and lower blades, both of which are to be beneath the surface of the lids or entirely in the passage and hidden from view. In this way the slit prevents the soft tissues from closing the opening of the tube or hindering the passage of the tears through the tube. It can be worn indefinitely.

If the stricture should not be absorbed, or if the dilatation with probes is deemed necessary, they can be easily passed down by the side of the tube. I have nine of these tubes now in use. The one I showed you a few moments ago I removed on yesterday. It had been worn over two years by a book-keeper without the slightest annoyance and without the knowledge of his office associates, and also without a recurrence of the trouble.

Believing the probes and dilating methods to be a failure, I operate and introduce a tube as soon as these cases come under my care. If dead bone or tumors are present, they should be removed and the tube introduced.

A SIMPLE PRISMOMETER.

BY SHIRLS JACKSON, M.D.

PITTSBURG, PA.

It is not intended here to enter upon the thorny discussion of one-fourth degree prisms, but to call attention to the frequent errors of one-half degree or more in prisms of low degree, bearing the same num-

ber, and reposing in the same trial-set, the statements of the manufacturer to the contrary notwithstanding.

However accurate the trial-lenses may be, little thought seems to be given by the manufacturer to the accuracy of the prisms. Frequently the prisms are rotated, and the base apex line wrongly marked so that the prisms may neutralize. The effect of these errors upon diagnosis is obvious.

While the difficulty of grinding prisms to a predetermined refracting angle has necessitated the measurement of each glass separately to determine the angle of deviation, with which alone the ophthalmologist is concerned, nothing but expensive and elaborate appliances have been offered with the assurance of anything like exactness.

Those who have once tried a prismometer are aware of its convenience and accuracy, but however useful in the laboratory, the more elaborate appliances are out of the question in practical ophthalmology.

For the surgeon who has only an occasional use for a prismometer and for opticians who care to fill prescriptions for prisms, accurately, the simple instrument shown in the illustration is made by Queen & Co. from a model used by the writer. It measures the angle of deviation in prism-dioptres as advocated by Prentice and is a modification of his instrument. From the reading in dioptres, the angular deviation in centrad or degrees and the value of the refracting angle may be known at a glance, from the accompanying table of equivalents.

The prism to be measured is clamped between the end-gauge and the face-plate, as shown in the illustration, a spring holding the prism in position. Sighting through the slot in the face-plate, and holding the instrument in such a position that the prism bisects the observer's pupil, two images of the index-plate will appear. The prism is now rotated until the tops of the two images form one unbroken, horizontal line. The base-apex line is then indicated by one of the horizontal lines upon the face-plate and from one of these lines the base-apex line may be traced in ink upon the prism for future reference. With the prism remaining clamped in this position, and the upper edge of the prism still bisecting the pupil, the index-plate is again observed and as the zero-line is red, and extends below the scale, its deflection upon the scale is readily noted. The index-plate is glided along the bar until the zero-line has been deflected to the one-centimeter line¹ upon the scale. The deviating power of the prism may then be read in dioptres, tenths, and hundredths, from the graduated bar at the point where the index-plate is stopped.

¹ A greater or lesser unit of deflection than 1 centimeter upon the index plate may be chosen for convenience, remembering to increase or diminish accordingly the reading from the bar; as with a 15° or 20° prism a deflection to the 2 centimeter line upon the index plate may be allowed and the reading taken as before from the bar, but it will have twice the value and must be multiplied by two. With fractional prisms below 1° a deflection to the 1 millimeter line only should be allowed. As the reading will be ten times too great the decimal point must be moved one place to the left, a reading of 2.50 being written .25 P. D.

With ordinary ophthalmological prisms this is all that is necessary.

To center a lens, clamp it in the instrument, and slide the index-plate in focus. The zero-line will appear broken. Rotate and shift the lens until the zero-line is strictly rectilinear. Draw a line upon the lens corresponding to the slot in the face-plate. Rotate the lens 90 degrees and repeat the operation. The intersection of the lines marks the optical center of the lens, and if a cylinder is present, its axis exactly corresponds to one of these lines. If the geometrical center of the lens does not coincide with the optical center, prismatic effect is present. Marking the geometrical center in red and placing it directly over the slot in the face plate, the zero line will appear broken. Several square prisms are slipped behind the face plate; the one that restores the continuity of the zero line gives the deviating power of the contained prism. The power of the contained prism at any point upon the lens may be determined, and marked from the slot. If the neutralizing prisms have not the exact intervals required, or if square prisms are not at hand, the next interval above is placed behind the face plate, and rotated until the zero line is restored. Care being taken to keep the prism exactly in this position, the lens is removed, and the prism measured in this position. The exact deviating power for that point on the lens that was opposite the sighting-slit is then known.

This use of neutralizing prisms is more than sufficiently accurate, and eliminates the calculation necessary to correct a direct reading from a spheroprismatic lens.

Opticians keep in stock, packages of uncut (square) prisms, from which, owing to the usual variations from exactness, the surgeon may select with the instrument, a set of metric prisms that when edged up, will be exact, inexpensive and of all desirable intervals.

SELECTIONS.

The Urine After Anesthesia.—The influence of various general anesthetics upon the processes of metabolism in the body has been repeatedly studied both upon clinical material as well as by means of animal experiments. In this way the advantages and dangers of this or that anesthetic have been more or less thoroughly established. The action of chloroform and ether upon the kidneys has received special attention. Post-anesthetic albumin, uria and glycosuria have been repeatedly investigated, with the result that the liability to nephritis after anesthesia in persons with healthy kidneys has been shown to have been in the past very much exaggerated. Among the recent contributions upon this important topic may be mentioned Weir's¹ "Studies of the Influence of Ether Upon the Kidneys." In 1890 Weir² presented the results of an examination of forty cases of ether anesthesia with the result that in about one-quarter of the cases in whom the kidneys were previously healthy slight transitory albuminuria occurred after the narcosis. Feuter's³ conclusions, based on clinical and experimental observations, was that ether has no perceptible influence on the healthy animal kidney, that it is not dangerous in persons whose kidneys are slightly diseased, and that albuminuria but very rarely occurs after ether anesthesia in persons with healthy kidneys. Butler⁴ found albuminuria but once after 500 ether narcoses. Körte⁵ found albumin in the urine only six times in 600 narcoses in healthy persons. In seven cases where albumin preëxisted in the urine it was not increased by the etherization. Wunderlich⁶ concludes that in an already existing case albuminuria is frequently increased by an ether narcosis; that this is twice as common in chloro-

form anesthesia in the proportion of 11.5 to 6.9 per cent. Wunderlich says that an ether nephritis may be excluded from surgery. Wood⁷ thinks that if the kidneys are diseased, increased "irritation" may occur from ether narcosis; in animals Wood found etherization to produce cloudy swelling of the renal epithelium, but Selbach⁸ found that prolonged etherization, repeated on many successive days, never produced nephritis, and out of ten animals, slight fatty degeneration of the renal epithelium was found but once. Weir's⁹ last communication upon this topic contains the following summary of results:

1. Normal before and after 254 cases.
 Abnormal before, but without increase in
 albumin or casts after 7 cases.
 Abnormality lessened after 3 cases.

264 cases.

Or about 87 per cent.

2. Normal before, afterward abnormal . . . 31 cases.
 Abnormal before, abnormality increased . . 8 cases.

39 cases.

Or about 13 per cent.

Weir also studied 112 cases that had a record of the temperature after etherization and came to the general conclusion that elevation of temperature, the cause of which it was thought would aggravate the work of the kidneys and lead to, in conjunction with the narcosis, abnormal excretions, does not appear to have any positive influence on the point. Etherization in the vast majority of cases in normal kidneys, and even in abnormal kidneys, consequently does not bring about any detrimental effects as far as albuminuria is concerned. Concerning post-anesthetic glycosuria, it may be said that Wunderlich¹⁰ and others have never been able to find sugar after narcosis, where glycosuria did not exist before.

Kast and Mester¹¹ report that after prolonged chloroform narcosis in healthy individuals a prolonged disturbance in the metabolism of albuminous substances occur similar to those induced by phosphorus poisoning, may develop a sulphur-containing substance, similar to cystir, being excreted in considerable quantities. Becker,¹² in Bonn, described some instances of rapidly fatal diabetic coma subsequent to narcosis, which he was inclined to believe were due to acetonuria, and this observation gave him the idea to investigate the question whether or not narcosis can lead to the production of acetone in healthy persons. Becker,¹³ therefore, set about to systematically examine the urine of practically all the patients anesthetized in the surgical clinic of the Bonn University, for sugar, albumin and acetone before as well as after the narcosis. The method used for the demonstration of acetone was the qualitative test of Legal, which is made as follows: To a few ccm. of filtered urine are added a few drops of a freshly prepared, 10 per cent. watery solution of nitro ferrocyanide of sodium, the mixture is then made alkaline by adding a solution of sodic or potassic hydrate when a burgundy-red color appears. Then a few drops of strong acetic acid are added and, if acetone be present, a purplish tint is formed at the juncture of the acid and the mixture. Becker made the unexpected observation that in the majority of healthy persons there arises an acetonuria of varying duration after narcosis. The following table will give a birdseye view of his results:

Anesthetic.	Number of patients.	Positive.	Negative.
Ether	195	132	63
Bromether	16	7	9
Chloroform	5	5	—
Ether followed by chloroform . .	33	22	11
Bromether followed by ether . .	2	1	1

The duration of the narcosis did not seem to have any influence on the occurrence of the acetonuria; the same is also true as regards the nature of the disease and of the operation—whether bloody or not—in children acetonuria seemed to be more frequent and also more marked than in adults. As a rule the acetonuria disappeared on the second, third or fourth day, but in some instances it continued for eight or nine days. In a case of perineal section it was possible to show that twenty minutes after the beginning of the anesthesia the urine already contained acetone, having previously been free from this substance. In a number of cases containing acetone in the urine before the narcosis the acetonuria was found to be increased after the operation, and

in three diabetics the narcosis increased preëxisting acetoneuria very considerably.

Concerning the significance of acetoneuria in general, it has been shown by v. Jacksch¹⁴ and others that it arises from the disintegration of albuminous substances, and consequently post-narcotic acetoneuria is a symptom that points to an increased destructive metabolism of albuminous compounds during and also after the anesthesia. In healthy individuals this post-anesthetic acetoneuria seems to be without any evident dangerous consequences, but in diabetics the increased excretion of acetone after anesthesia shows that in such cases narcosis is connected with greater dangers than in healthy patients.

In one case of bromether intoxication, abnormally large quantities of acetone were excreted, which led Becker to believe that in this case serious disturbances of tissue metabolism had been induced. Finally, the interesting and new observations by Becker upon acetoneuria after anesthesia may be summarized in these conclusions:

1. In healthy persons acetoneuria, lasting from a few hours to a few days, may appear after narcosis. In two-thirds of the cases, Legal's reaction with filtered urine gave a positive result.

2. Preëxisting acetoneuria is increased by the ordinary anesthetic agents.

3. In a case of severe bromether intoxication excessively large quantities of acetone were excreted.

4. Acetoneuria after anesthesia is a symptom of increased disintegration of nitrogenous compounds.

Third Annual Report of the Hospital and Dispensary at Chemulpo, Korea.—The third annual report (1894) of St. Luke's Hospital and Dispensary at Chemulpo, Korea, has been received from Dr. E. B. Landis, the physician in charge. It states that, owing to the fears of the inhabitants caused by the presence of Japanese troops, many fled from the city, and during July and August half of the native houses in Chemulpo were empty.

The cases treated number 4,463; of these 159 were of the respiratory organs, 407 of the intestinal tract, 16 of the urinary organs, 121 diseases of the skin, 213 injuries, deformities, etc., and only 50 cases of venereal diseases. The term pestilence is used because it is a translation of the native word; there were 68 cases of the disorder. The disease occurs in the spring and early summer, and the mortality is very high. The fears of the natives cause them to avoid it as much as possible. Relatives are compelled to leave the house until the patient recovers, if he is fortunate enough to do so.

No one can come in contact with the natives without seeing evidences of the ravages caused by smallpox. People blinded, crippled, and pockmarked are seen everywhere. An increasing number of children are brought for vaccination. The Koreans have a method of inoculating children by introducing virus from a smallpox patient into the nostrils of the child; but the mischief caused by this is only exceeded by that of the disease itself.

The native treatment of a forming abscess is by a kind of sticky mass, resembling shoemaker's wax, the chief ingredients of which are centipedes and pine-tree sap. This is applied to the forming abscess. The pus can not find its way out through this, and therefore burrows down through the more yielding tissues and finds its way out through half a dozen openings. If not seen and properly attended to, it sometimes goes down very deeply, resulting in periostitis and necrosis. When a patient presents himself for treatment there is generally a mass of diseased flesh with several sinuses leading down often quite deeply. This must be fully incised and then washed out, antiseptically.

A number of cases under the head of incised wounds were caused by the stem of the native pipe, a long piece of bamboo with a tapering mouthpiece of metal perforating the back of the throat. This accident is caused by a man's stumbling or falling while smoking, the stem being forced through the tissues, often with fatal results.

Among the cases reported was one of leprosy. The patient was a man who came from the south, begging for relief. It being impossible to place him in the hospital, a temporary place was obtained for him at some distance from the settlement. The case was one of tuberosa form; leontiasis was very marked. When he came the disease was quite advanced, with nodules scattered all over his face, and ulceration of the hands and feet already begun. He was treated with Chantmoogra oil and iodids, but without avail; he gradually grew worse and finally died.

Sanitary matters among the Koreans are in a very rudimentary state. The foreigners and Japanese are not teaching the Koreans any very useful lessons in this respect. Great care is taken to keep the streets in good order, but the gutters, or so-called drains, are used as cesspools or places for dumping all sorts of offal. Once in a while a pretense is made of cleaning them, but the only time when they are in proper condition is when the rainy season washes them out. Dr. Landis says the coming year (1896) will be an unhealthy one. The eight Provinces as well as the two large islands of Quaelport and Kanghoa were represented in the hospital during the year. Boats from all parts of the country are continually arriving, and important medical missionary work is being successfully carried out.

Dr. Landis has given the most untiring devotion to his duties, and his influence in the cause of medical science has been very great.

SOCIETY PROCEEDINGS.

Chicago Academy of Medicine.

Regular meeting held at the Union League Club Dec. 15, 1895.

DR. A. E. BALDWIN was chosen Chairman.

The first paper was read by Dr. William L. Ballenger, entitled,

ANGIO-NEUROTIC EDEMA.

He said that angio-neurotic edema was a so-called disease characterized by an acute, circumscribed, non-inflammatory swelling or edema of transient duration. It has been variously named, according to writers' ideas of etiology, pathology or symptomatology, as acute circumscribed edema; acute idiopathic edema; essential edema; periodic swelling; urticaria tuberosa; giant urticaria, or giant swelling; acute non-inflammatory edema, etc., etc.

Symptoms.—The edema appears suddenly—sometimes with and sometimes without prodromal symptoms—and is transient. A common seat is the face, the eyelids being most frequently affected. The lips and cheeks may also be involved. The Schneiderian membrane, the pharynx, uvula, epiglottis, larynx and lungs may be the seat of swelling. The hands, arms, legs, genitals and trunk, indeed, any of the mucous membranes and any portion of the skin may be selected as the site for edematous swelling, although it seeks by preference the most lax parts. It may appear in one part and later appear in another. It is usually associated with other symptoms or diseases, as hay fever, urticaria, headache, gastro-intestinal disturbances as watery vomiting and colicky pains, itching and redness.

Etiology. The etiology may be studied under the following subdivisions: 1. Predisposing causes, as *a*, heredity; *b*, previous and present condition of disordered health; *c*, overwork either mental or physical; *d*, exhaustion from disease, exposure or exertion; *e*, and last, but not least important, the neuropathic taint.

There is a growing conviction among neurologists that the reflex centers have been much abused by writers in accusing them of much that properly belongs to the central nervous system. We are coming more and more to recognize the intimate relationship existing between mind and matter, and perhaps many phenomena which we attribute to what may be styled the animal mechanism, have their origin in cerebration, though the act be an unconscious one.

While there is undoubtedly a close relationship between urticaria and simple acute edema, as there is between all neurotic phenomena, yet there is a somewhat different pathology attending the various manifestations. Some of the cases now referred to as angio-neurotic edema are probably cases of urticaria and tend to confuse the judgment of the student. In Matas' case there was malarial toxin as an exciting cause, and

the tone of the tissues was impaired by the ravages of long-continued disease until the soil was ripe for angio-neurotic manifestations. The edema recurred daily from 11 to 12 A.M., on the upper lip, causing great disfigurement during the brief time of its stay. It was finally cured by quinin as for malaria.

Osler's classic study of five generations, shows one affected with angio-neurotic edema in the first generation, one in the second, five in the third, ten in the fourth, and three in the fifth. Edema was not inherited by these people, but an impaired cell structure and activity which manifested itself as an edema was inherited. Along with this tendency, environment and suggestion acted as exciting causes.

The author then closed his paper with a report of a case coming under his own observation, and added that he believes it is a mistake to write or speak of angio-neurotic edema as a disease, for it is not a disease; it is but an expression, a symptom of some stimulus acting upon impaired cell structure.

DISCUSSION OF DR. BALLENGER'S PAPER.

DR. G. FRANK LYDSTON—Dr. Ballenger's paper is so very complete that there is very little to add to his remarks. I agree with him in the assertion that in so-called angio-neurotic edema some underlying organic peculiarity of the individual is essential. I believe the same proposition is true as regards ordinary urticaria. I have long been satisfied in my own mind that so-called giant urticaria and ordinary urticaria are congeners. I have no theory to advance regarding the essential condition underlying these forms of skin eruption. There is perhaps, after all, no better term than idiosyncrasy which can be used at the present time to explain the varying results of the ingestion of various toxic substances in different individuals. There must be some explanation for the fact that of several individuals who have ingested shell-fish in a more or less advanced stage of putrefaction, or over-ripe tomatoes, one should develop severe urticaria, while the others escape. The toxic materials which enter the system in each instance are precisely the same, granting that a series of individuals ingest the same kind of objectionable food. It is a matter of common experience that in certain individuals the freshest shell-fish will invariably develop urticaria. We can not explain this any more than we can explain why certain individuals who inhale the pollen of plants, or on entering a room in which a small amount of powdered ipecac is floating in the atmosphere, develop symptoms similar to hay fever. These symptoms referable to the mucous membrane, it seems to me, are congeners to urticaria. It is useless to deny the existence of so-called idiosyncrasy in the direction of a peculiarity of nervous organization which predisposes to urticaria and its congeners. The effect of toxins as an explanation of its exciting cause, is compatible to the effect of various drugs which we use in medicine. We know that copaiba, quinin and many other drugs produce eruptions in certain individuals, and there is nothing, so far as I know, but individual predisposition to explain this unless the vicarious functioning of the skin necessitated by imperfect renal action, the loss of balance manifesting itself under these circumstances by dermal irritation. There are certain local influences which will bring about urticarial manifestations without the necessary intervention of individual predisposition. This is eminently true of insect bites.

I had an excellent opportunity to study the effects of insect bites during the riots of the summer of 1894. A number of the troops under my charge at the Union Stock Yards were bitten by horse-flies, which were abundant and particularly voracious in that locality. I had fifteen cases of septic bites which I had under careful observation. The first manifestations were marked localized edema, with the characteristic waxy semi-translucent appearance of the urticarial wheal. This was followed by an inflammation of an erysipelatous character, with suppuration and considerable destruction of cellular tissue quite similar to that which is presented by ordinary carbuncle. Taking insect bites as the basis for argument, we have also another evidence in some cases of the importance of individual predisposition. We find, for example, that ordinary mosquito bites in some individuals result in the formation of large urticarial wheals, while in others slight or no irritation results. Observations of insect bites of the skin on the effect of urticarial eruptions are important in reference to the possible relations of toxins to ordinary urticaria. Reverting to drug eruptions, as an illustration of individual predisposition I recall the case of a lady who developed, after the application of belladonna ointment of mild strength, an erythematous eruption which practically covered the entire body, and was as marked as ordinary cutaneous erysipelas. I experimented on three different occasions with the same result.

It has seemed to me that gastro-intestinal irritation is by no means essential to the production of urticaria; indeed, in some

cases in which marked urticaria develops as a result of the ingestion of certain unwholesome food substances, no symptoms of gastro-intestinal irritation whatever are present. I know, for example, of a gentleman who, upon the ingestion of a small quantity of honey, will develop a severe urticaria. Another case, under my observation, would have severe gastralgia upon the ingestion of so small a quantity as a half-teaspoonful of honey. The gastralgia would come on speedily after the ingestion of the honey, and the attacks occurred too frequently under my own observation to admit the possibility of error.

The term angio-neurotic edema is by no means satisfactory, but if the underlying condition in ordinary urticaria and so-called giant urticaria is the same, I believe it would be best to classify them as similar conditions. The term angio-neurotic edema is as comprehensive as anything that has thus far been suggested.

DR. W. L. BAUM—The subject of angio-neurotic edema is an extremely interesting one, not only on account of the various conditions under which it may appear, but also because of the many articles which have been written from time to time relative to its etiology. The vast majority of these cases otherwise enjoy good physical health. Neither the seat of the lesions, nor their extent, shed any particular light upon the etiology. I can hardly agree with Dr. Ballenger in the statement that the condition is necessarily due to an alteration in the endothelial cells of the vessels, for if there were some abnormal changes then like etiologic factors employed at various times would be always bound to bring about like results. We frequently find that an emotional disturbance will bring about a sudden attack of angio-neurotic edema. Take, for instance, the case reported many years ago where an improper proposal was made to a young lady at a dance: within a few minutes her whole body was covered by a urticarial (giant) eruption. Many such cases have not only been reported, but are seen in every-day practice by the dermatologist, and are striking illustrations of the fact that the emotions and neurotic disturbance in general may have a powerful influence in bringing about eruptive conditions. On the other hand, it must not be forgotten that a large number of these cases develop after the ingestion of certain foods, and a great variety of foods may produce angio-neurotic edema.

As regards hereditary influences, it can be taken for granted that the changes, whatever may be their character or idiosyncrasies, are purely of a neurotic type. Whether it be a reflex condition resulting in dilatation of the vessels through paralysis of the vasomotor contractor nerves, or an irritation of the vasomotor dilator nerves, will probably never be satisfactorily demonstrated. The fact remains that the vessels do dilate, and that we have a serous, sometimes a sero-sanguinous exudate present, which gives us a variety of symptoms which may be brought about by the same etiological factor. Very frequently the gastric disturbances, which are so often named as the exciting causes, occur subsequent to the appearance of the edema. If we take into consideration that this change occurs sometimes on widely separated portions of the skin, and sometimes upon almost all portions, it is reasonable to suppose that the eruptive condition also occurs upon the mucous membrane of the nose, etc. For instance, we frequently notice that the soft palate and uvula are involved in this condition, and undoubtedly the condition occurs in the stomach, as well as intestinal tract, as exemplified by frequent attacks of enteritis; and the cerebral symptoms can be easily accounted for on the supposition that similar local conditions are also produced. There is no doubt in my mind that the angio-neurotic condition is in itself only a symptom, and that its existence is not dependent upon structural changes, but upon neurotic conditions, and it may have as its exciting factors a large and almost endless variety of causes.

DR. H. M. BANNISTER.—I have been very much interested in Dr. Ballenger's paper. When I published my case at first, it was simply because it was novel to me, and I have lately congratulated myself on the judiciousness of the title I then gave it: "Erythema or Urticaria," more especially since reading within the last two or three days an article by Dr. Osler, in which he refers many of these angio-neurotic conditions back to the types he discusses in his paper on exudative erythema, and, I believe, he refers his celebrated hereditary angio-neurotic family to this form. Henoch's first case of what I take it has been called Henoch's purpura, and which I stated was given as purpura, is included by Collins and Lovett in the literature of angio-neurotic edema, which literature, I believe, has been made to include many cases of conditions very different from each other, and which are not properly to be classed under this head.

As regards the pathology of the disorder, I presume I should agree with Dr. Ballenger in the main, though I have considered most of the cases as belonging to or closely related to urti-

caria. My last paper was written because the disease had been adopted by, or had been thrust upon neurologists, and it was published with the idea that it might help to refer it to its proper place. I believe it to be a neurosis of the integuments, but I doubt whether dermatologists themselves know how to properly place it as a distinct clinical entity.

DR. HUGH T. PATRICK. I have been greatly interested in the satisfactory paper of Dr. Ballinger, and he seems to have left very little room for criticism, but I would have been better satisfied if he had more clearly defined angio-neurotic edema. This slight dissatisfaction has been intensified by the discussion. We have had classed under this head almost everything from edema of glottis to hereditary trophoneurosis, and from the tumefaction of insect bites to simple and giant urticaria. My own difficulty has been to conclude what is and what is not to be classed as angio-neurotic edema. I had hoped to see the line drawn this evening. I have not been able to do so myself, for we can follow these troubles step by step from simple transitory blushing and paling to the most pronounced and persistent edema and pseudo-edema. In any normal individual, sharply stroking the skin with a blunt instrument will cause first a white line, and then a red one; in some peculiarly susceptible it will cause an elevation, and in others decidedly abnormal it will cause marked swelling which will persist for hours and can be reproduced after twenty-four or forty-eight hours by simply rubbing the surface with the hand. In the same way, the bite of an insect will produce in one person a slight wheal, in another a swelling and edema of the entire extremity. An auto-intoxication from the gastro-intestinal tract will cause in one, slight malaise; in another an outbreak of urticaria. I saw some time ago a lady subject to facial neuralgia, and every attack was accompanied by a marked edema of the face, as in a person with the proper predisposition, or, as Dr. Lydston prefers to call it, idiosyncrasy: a very slight irritation from without or within may be the determining cause of a localized edema, so this same result may be induced by an influence emanating from the brain, not a toxic but a psychic cause; in other words, a local edema, exceedingly difficult to separate from angio-neurotic edema, may form part of the symptom-complex of hysteria. This has been known since the days of Sydenham and is clearly emphasized by Brodie in his interesting little monograph on Local Nervous Affections, published, I believe, in 1837. Here, too, we can trace the degree of disturbance from simple blushing and perspiration from mental causes through erythromelalgia and Raynaud's disease, some cases of which have been conclusively shown to be of psychic origin, to transient and even persistent edema. In substance then, I must agree with the reader of the paper, that angio-neurotic edema may exist in many different ways. I do not think it can stand even as a clinical entity. For its definite classification we need facts, and these facts are not yet forthcoming.

DR. BALLENGER (closing). It was with much hesitation that I presumed to write upon a subject which is generally conceded to belong to the neurologist and dermatologist, but many of the so-called angio-neurotic edemas occur in the nose and throat, and therefore should claim my attention as a rhinologist and laryngologist.

Dr. Bannister believes the so-called angio-neurotic edemas are but forms of urticaria. I agree with him to the extent that many cases reported as urticaria are, indeed, not urticaria, but are cases of angio-neurotic edema. This is suggested in the thesis. While the exciting causes and possibly the predisposing causes may be almost identical, yet there is a difference in the pathology. Dr. Baum questions the impairment of the intima of the small blood vessels. Now, if we accept the simple vasomotor theory we must look upon the vessels as so much elastic with epithelial plates or brick, which regulate the amount of nutrition which is allowed to ooze through. When the vessels are dilated the plates are pulled apart and a free flow of lymph follows. I can not bring myself to think of the epithelial cells lining the vessel walls as mere inert matter acting as impediments to the transudation of lymph, for when we remember that they throw out arms or finger-like processes and embrace bacilli, we must concede a high degree of autonomy, and may reasonably expect an impairment of them to result in a modified functional activity. An acute hyperemia does not bring about an edema even though it be quite prolonged. I am well aware of the fact that I can not prove my position and that it can not be disproven. I only hold to the hypothesis which to me seems in harmony with the known facts.

In reply to Dr. Patrick's query as to why I did not more specifically define angio-neurotic edema I will say that I look upon it, not as a disease to be defined but as a symptom, an expression of an exciting cause acting upon impaired (not dead)

tissue. In other words, an exciting cause alone can not produce an acute edema; there must co-exist an impaired cell structure in the blood vessel walls. By impaired cell structure I mean that its normal activity is interfered with, and not that its structure is destroyed. This impairment may continue for only a short time and may occur through some trophic process which may have its origin from some impression made upon the brain; or, as is more common, it may arise from irritation of the nerves or centers controlling the cells, or possibly from direct irritation of the cells, although from the light of recent investigations made by Metchnikoff, this is less prebable.

In conclusion, I believe angio-neurotic edema should not be thought of, spoken of, or written about as a distinct clinical entity. It is my habit to think of it as an acute transient circumscribed edema resulting from some stimulus either psychic, chemic, or traumatic, acting on neurotic or impaired animal structure.

DR. E. A. HALSTEAD read a paper on

FLOATING BODIES IN JOINTS.

He said by floating bodies in joints, or, as they are frequently termed, joint mice, he meant bodies of varying structure usually composed of bone, cartilage, masses of fibrin or fat, or fibrous tissue which are either loose in the joint or are attached to some part of the joint surface by pedicles. By far the greater part of these bodies is found in the knee-joint, so that when we speak of joint bodies we usually refer to the knee as the seat of disease. They next in frequency are found in the elbow-joint, and rarely in the ankle and wrist. The explanation of their frequent occurrence in the knee-joint is that the joint has a very large surface, and that by its position it is greatly exposed to traumatism.

The first systematic study of these bodies was made about 250 years ago by Pechlin, a Swedish surgeon. Since then numerous cases have been reported and a great many theories advanced in explanation of their origin. Of late years, careful microscopic examination of specimens removed by operation, and found on postmortem, has done much to clear up doubtful points in the etiology of these peculiar bodies.

The author reported three cases which had lately come under his observation.

Etiology.—The cause of loose bodies in the joints has been a much disputed question. Of late considerable advance has been made in determining the exact causation of individual cases. In the past, most writers ascribed a common cause for all these bodies, whereas we now know that there are a number of factors concerned in the etiology, and different cases have a variety of modes of origin. Exact clinical histories with careful classification on a histologic basis have done much to clear up many mooted points in the etiology of these peculiar bodies. Using Volkmann's general classification, we have *a*, those that are found in otherwise healthy joints, the disease, if any be present in the joint, being only that occasioned by the presence of these bodies; *b*, those that are found in diseased joints.

The author then considered the symptomatology and diagnosis at considerable length. Coming to the treatment he said that it may be of historical interest to mention some of the methods of treatment that were employed in pre-antiseptic days. Chassaignac mentions the following methods that were employed:

1. *Palliative.* *a*, Fixation of the loose body by compression, so that it may become attached to the capsule; *b*, fixation by passing needles through a part of the capsule; and *c*, fixation by subcutaneous ligature.

2. *Radical Methods.* *a*, Removal through direct incision; *b*, incising the skin at different levels; *c*, through subcutaneous operations performed at two sittings, the skin from a distance being displaced over the body; incision made through the skin and capsule, the body allowed to escape into the subcutaneous incision, from which it was removed at a later time after the capsule had healed.

During the pre-antiseptic period the mortality connected with these radical methods of treatment was very high. Bell recommended amputation in those cases where an operation was indicated, in preference to opening the knee-joint. The mortality at this time was about 33 per cent., and of those who escaped with their lives a great number went through life with a more or less ankylosed joint, as a result of septic infection. It is scarcely worth while to mention that the only method of treatment of to-day is to remove these bodies by direct incision.

The author concluded:

1. That the etiology of some of these bodies is yet not fully understood; but that the condition described by König under the name of osteochondritis desiccans explains the most of those that are found in otherwise normal joints. This deserves further investigation.

2. That few, if any, are the direct result of violence.
3. That the most pronounced symptom is the sudden onset of severe pain in the joint with locking of the joint, usually in a nearly extended position, this being followed by acute inflammatory process in the joint involved.
4. That lengthening of femur (in movable bodies in knee) may occur as a result of irritation produced by the pressure of these bodies.
5. That the only treatment for their condition is the removal by direct incision, preferably under cocaine anesthesia, as soon as diagnosis is made.

DISCUSSION.

DR. G. FRANK LYDSTON—The essayist has left very little to be said on the subject of "Floating Bodies in Joints," he having practically covered the more important points of the contributions pertaining thereto. I, of course, understand that he has not intended to dwell upon tuberculosis as the cause of movable bodies in joints. The ordinary floating cartilages or foreign bodies in joints are not of tubercular character, but we meet with very many cases in which movable bodies are found, and in which tuberculosis is the only explanation; and the more recent researches in this direction have especially emphasized the important relation of tuberculosis to these conditions. Personally, I have always regarded the majority of these cases as of inflammatory origin. I do not believe traumatism is as important a factor in the production of floating bodies in joints as is ordinarily supposed. In many instances the patient presents himself with a history of traumatism, but this means that the first injury produced by the floating body getting between the joint was supposed to be the cause and not the effect of the floating body. It is easy to understand that a floating body in a joint is not likely to give rise to any disturbance unless it is associated with some condition which impairs the functional integrity of the joint structure, until such time as a favorable opportunity is afforded for its action as a foreign body. During perhaps some movement of the joint, which the patient recalls as somewhat unusual, the foreign body slips between the joint surfaces, produces contusion, and subsequently more or less acute synovitis of greater or less degree of severity. The patient under such circumstances is very likely to present himself with a history of strain or other injury to the joint which has produced an inflammatory condition for which he consults us. The free bodies found in the joints which result from tubercular degeneration are numerous and of a cartilaginous or even-bony feel, and can be readily outlined with the finger in many instances.

Laying aside the post-mortem or post-operative pathologic appearances, we have clinical support of the tubercular nature of these floating bodies in the fact the ordinary treatment of joint tuberculosis by injections of iodoform emulsion frequently results in the complete disappearance of the bodies.

I congratulate Dr. Halstead upon his excellent and valuable contribution to a subject which has not been as carefully studied or as well understood as could be desired.

DR. W. XAVIER SUDDUTH read a paper entitled "Suggestion as an Ideo-Dynamic Force."

The Chairman called upon DR. PATRICK to open the discussion. The doctor said: I am in no sense a psychologist, practically or otherwise, and as the paper has been essentially a psychologic one, I do not feel in the least competent to discuss it. But in accordance with the legends of the Academy, I would beg leave to decidedly differ with the reader of the paper on one point. He said in substance that suggestion is the legitimate child of science, born in the laboratories of the biologist and experimental psychologist. I would submit that it is the legitimate child of empiricism, born of the practical experience of fakirs and physicians, hundreds of years before biology and psychology were dreamed of.

DR. H. M. BANNISTER—I regret being called upon to discuss the subject of Dr. Sudduth's paper, as I do not feel prepared to do so. I can not say that I agree with him, for it seems to me he goes too far in his claims of the value of suggestion in therapeutics, and I doubt whether he will ever realize his visions of its replacing drugs to the extent he anticipates. I do not see, for example, how we are going to be able to come to the condition of voluntarily restraining the purely vegetative functions and the movements of the heart by mental effort. I should have to read his paper, however, and carefully considered it before I felt able to perfectly discuss it. But in any case my conception of the power of the human will over bodily conditions falls very far short of what I understand to be his, from the paper he has read.

DR. WM. F. WAUGH—Great discoveries in medicine are apt to be received with disfavor at first. Vaccination was violently opposed by the medical profession; hydropathy and electricity were exploited by empirics until the success of the latter com-

pelled the physicians to adopt these methods, which, scientifically studied and applied, have become very much more valuable than when operated by the ignorant. On the other hand, Koch's tuberculin and Bergeon's gas enemias were received with all but universal enthusiasm. Judging by its reception, hypnotic suggestion, as a branch of psycho-therapeutics, seems destined to repeat the history of hydropathy. To the general practitioner, suggestion is of great interest. When one has passed through the stage of enthusiastic faith in drugs, he will find that much of the success he attributed to them was really due to the patient's faith in the doctor: so that it is often difficult to determine what is the precise value of the drug.

Dr. Sudduth made one important statement, that hypnotized persons can not be induced while in that state to do things they would not do when out of it. This should be brought to the attention of medico-legal experts and the newspaper fraternity, as a very different view is presented by them. Indeed, the common conception of hypnotism, taken from the works of Dumas and Du Maurier, has about the same relation to the truth that the gorgeous palaces of the Arabian Nights have to a modern city residence.

DR. JAMES G. KIERNAN said he should have to take issue both with Dr. Bannister and Dr. Sudduth. The will, as was claimed by Dr. Bannister, was not as had been stated by Dr. Sudduth, a simple determining factor, but a complex. There is no will, strictly speaking, but wills. When these act in unity the normal condition exists. When the union is broken a large number of hitherto unconscious states rise into consciousness, producing for instance comparatively trivial notions which often plague the comparatively normal individual by the fact that he is obliged to rid himself of these by a conscious effort to do what was previously done automatically. That the brain received and registered a large number of objectionable matters unconsciously, was excellently illustrated in the insanity of pregnancy, during which refined women used not merely the gestures and actions of courtesans, but their very expressions. It was also illustrated in the cases in which ignorant persons had registered unconsciously expressions once heard from the Greek and Latin classics and had reproduced them during fever delirium, remaining totally unconscious of their source. The fact was, that while suggestion might act normally it certainly was most potent in the abnormal state, which was either hypnotic, or closely allied to it.

Dr. Sudduth in his claim that hypnotism and suggestion are most easily applied to normal beings, was supported only by psychologists whose opinion was of no value whatever as to the normal or abnormal, since two of those quoted had admitted on clearly insane testimony, whose nature they did not recognize, the possibility of the occurrence of ghosts. The vast majority of alienists and neurologists had found that not only was the unstable nervous system most easily affected by hypnotism, but that it was actually injured by it. This was excellently illustrated by Westphal in his experiments on animals, which he found became readily paralyzed after having been frequently hypnotized. That this must result would be obvious on an analysis of the vasomotor phenomena underlying hypnotism, and even suggestion. Rapid vasomotor alternations, such as resulted from the strong impressions produced by hypnotism, must and did derange the monarchic vasomotor centers with consequent deteriorating action, both on the walls of the blood vessels and on the parts supplied by them. The fact that the insane, as a rule, could not be hypnotized simply indicated the potency of counter-suggestion, in which way delusions acted. The insane of the abulic type were undoubtedly influenced by individual suggestion. It should be remembered also that the chief treatment of insanity, after all, consisted in suggestion, the discipline of the insane hospital acting in this manner in a beneficial way that no home-treatment could do, however skillful. The burden of proof still rested very severely on any attempt to prove any but a subjective influence in hypnotism. Suggestion undoubtedly played an enormous part in all medical practice, and was aided by surroundings tending to make the patient peculiarly susceptible to it.

With regard to the influence of suggestion in producing crime, in the vast mass of unstable degenerates no one could doubt such an influence, who had carefully perused the suicide records as to the relation of bizarre methods of suicide. An excellent illustration occurred several years ago. A patient was brought into a hospital with a suicidal wound inflicted in the vicinity of the femoral artery. The surgeon in attendance rather unwisely remarked to an overworked nurse, "If you make an attempt of that kind, cut a little lower down, you will reach the artery certainly." The man, who was depressed only from overwork, made the attempt, but fortunately did not profit by the instructions given. The case was announced in the newspapers, and three other instances in neighboring towns

occurred in rapid succession. The same thing is illustrated in the fire panics of theaters where, under the influence of the suggestion that the place is on fire, a large mass of people hear non-existent crackling flames, and smell non-existent smoke. A crowd is a being that acts but does not reflect, and hence is peculiarly liable to suggestion. The crowd is, however, not in a normal condition, for as separate units each individual would act on his own volition, and not on that of the crowd as a whole. That suggestion could be used in this manner to induce homicides, whether by an individual or by a crowd, no one who has studied lynch-law procedures can doubt. While it was true that if an individual had the secondary ego so developed as to act as a counter-ethical suggestion, he could not be induced by suggestion, whether in the hypnotic state or not, to perform crimes, in a large mass of mankind, and especially in the commercial world and among so-called society leaders, this secondary ego was very weak, and aside from the fear of law there would be nothing to act as counter-suggestion. Certainly the commercial people who could poison the insane with rotten food, who could "sweat" their employees into death, were not persons on whom the mere idea of taking another person's life would act as a counter-suggestion. These formed a large portion of the so-called intelligent normal class among whom Dr. Sudduth found such excellent subjects. On the other hand, that suggestion could act excellently as a moral factor was shown by the beneficial influence of the alcoholophobia movements and the Keely cure.

Dr. Kiernan was prepared to take issue also with Dr. Sudduth as to the duality of the mind or its manifestations. The opinions as to this had been fought out for centuries. St. Thomas Aquinas, for example, held the still powerful physiologic argument, that as mind was notoriously the product of material structure, as it produced material effects, and as it was affected by material influences, it must be a product of matter. Dr. Kiernan was prepared to admit from a careful study of morbid states, that strong mental influence could produce even organic alterations in structure. He had seen (not to speak of other instances) Raynaud's disease produced by mental shock. Suggestion and hypnotism had a certain limited value, but no more was done with it now than had been done by Mesmer and Puységur at the end of the eighteenth century, by Braid and Elliotson in England, and Brigham, Galt and others in the United States in the middle of this century. Dr. Crawford W. Long, the discoverer of anesthesia, had himself in company with Dr. Dugas, of South Carolina, experimented with hypnotism as an anesthetic before employing ether. All had found hypnotism of value, but all had found it too irregular an agent to be employed, as well as too dangerous in its secondary effects. THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION did not state the case too strongly when it lately announced the passing of hypnotism to the extremely moderate domain of therapy which it had occupied at the beginning of the century.

Annual Convention of the New Jersey Sanitary Association.

Atlantic City, N. J., Dec. 6, 1895.

The New Jersey Sanitary Association held its twenty-first annual session in the Brighton Casino, December 6. The session was opened at 2 P.M., by Dr. D. C. ENGLISH, of Brunswick, the President, Dr. STROCK as Secretary. SENATOR HOFFMAN welcomed the association on behalf of the Mayor of Atlantic City and extended to the members the freedom of the city, the ocean, in short whatever was in sight. President English in reply, alluded to the fact that this association had now attained its majority and had established its right to a position in the State. He mentioned as noteworthy the fact that Atlantic City appropriated \$20,000 a year to its Board of Health, thus showing its confidence in their ability, and enabling them to carry out the proper sanitary work of the city.

Dr. O. W. BRAYMER, of Camden, read a paper entitled "Sanitary Inspection of Factories." He said there was not law adequate to the work, nor the application of the scientific knowledge. The age of operatives is regulated by a law, but it is very doubtful if this is ever enforced, as may be judged by the judged by the appearance of many of the operatives. Inspectors are not paid sufficient to carry out this work; consumption is caused by the improper diet, dust and bad air of these places, hence many workers are disabled. Capital sees the importance of looking to protection from fire, and injury from machinery, but as the supply of work people is large, capitalists do not see the need of caring for their health. These points require education of the masses. We must teach sanitary science to the children; we must show the people that

health is wealth. Again, workrooms should be ventilated and disinfected when not in use. The water closets should be cleansed and put in proper order against the return of the people. Each employe should have a separate drinking cup. There should be a washroom where the hands can be washed, and thus the lunch not be eaten with dirty hands. Seats are needed for the women, the floors should not be allowed to remain in the filthy condition in which we usually find them. Statistics show that many factory work-people are diseased and die early.

Dr. STRICKLER in discussion said: He had made a careful inspection of a number of factories, particularly of textile fabrics. The number of operatives was nearly 40,000. Care should be taken at the very outset in the selection of a proper site for such a building. It should never be on made ground, and free from malaria. The drainage is generally into the sewers and cess pools: the plumbing is too often old fashioned, but in a number of instances it was as good as could be asked. A practical plumber is needed for such inspections. The cess pools rarely are ventilated and drain into a near-by stream. The drinking water, as a rule, was good, but very many drink freely of beer, which renders them unable to take the proper amount of food, and thus their strength is exhausted. The clothes worn are often not a protection from the weather, and it is a wonder that more do not die from the exposure which they voluntarily undergo. In several factories he found proper food was provided with excellent results in their ability to work. It is imperative that rest must be permitted by the provision of seats. In the case of women it was found beneficial by the better work done by them. Damp floors should not be tolerated. He was glad to be able to commend several places where the owners had wisely provided for the needs of their people. In these instances, the owners claimed direct benefits to themselves in the better quality of work obtained. He concluded that factories as a rule are not in a bad condition. He quoted one owner who claimed that he had known instances where the inhalation of oil had restored a consumptive to health.

Dr. J. R. LEALE read a paper on

PROGRESS IN PUBLIC HYGIENE.

This was a creation of the medical profession, born within thirty years. It had met with much opposition from prejudice at first, even among the intelligent. Now the medical profession claim it as their own. It is generally taught in the colleges. Only three States are without a department of health. To our disgrace the National Government has no department of health. Public water supplies are being protected and improved at great expense. Drainage and the disposal of refuse are claiming and receiving attention everywhere. Disinfection is becoming better understood and enforced. The food supply is a subject which now receives close attention as to its purity. Sanitation of shops, houses, factories, etc., is demanded. Within the past few years such progress has been made that six years have been added to the average of human life. No general epidemics now devastate the community. In view of the progress which has been made within a short time, we may confidently look forward to still more rapid improvement in the future with wonderful benefit to humanity.

A telegram was received from Governor-elect Greggs, regretting that absence from the State would prevent his presence at the convention.

Prof. WILLIAM B. ATKINSON, of Philadelphia, was invited to sit as a corresponding member.

The first paper of the evening session was entitled

THE HYGIENIC SUPERVISION OF SCHOOL CHILDREN.

by BARON NILS POSSE, Principal of the Boston Gymnastic Institute. He first spoke of the importance of knowing and understanding what was to be supervised, then who was to do it. The temperature of the school room must be regulated; when it is too hot the pupils are not able to perform the work properly. The clothing must be comfortably easy, so as not to interfere with the movements. See that the ventilation is correct. Windows are for air as well as light. Fresh air need not be cold air. This is a point upon which there appears much want of understanding. Next look to the seats and desks; the back must be supported, especially the small of the back; each scholar must be suited with a chair and desk, otherwise come spinal curvatures and other similar troubles. This perhaps is the most important yet least regarded point. Recitations should not be continuous, but at the end of every three-quarters of an hour a rest of some minutes should occur. Overwork produces poor students. Perhaps it would be better to not permit each recitation to exceed half an hour. Arrange the work so that most of it will be in the afternoon; for this is a better time for work than the morning when just risen from

sleep. By afternoon the system is thoroughly aroused and ready for work. Physical training is of vast importance, but properly guarded and never to excess. Here is wherein so many instances the training is wrong. When a child evinces signs of failing, it should be dismissed to play, to seek the fresh air or to rest, as the case may demand. Education is of no possible use without health. The gymnasium is a useful and valuable adjunct to every school.

In discussing this valuable paper, Dr. Barringer asked what would be thought of placing a young lady in a seat suitable for a child of 6 years. We must fit the furniture to the pupils. There should be single adjustable desks and seats. It is not the expense that we should consider but the results, regarding it as a profitable investment from which we may expect good returns. Teach the children cleanliness, and many good things follow in its train.

SUPERINTENDENT V. L. DAVEY, of East Orange, said ventilation is now attended to, but only in cold weather. In October and May, when it is of more importance, it is utterly neglected. Contrary to the usual impression adjustable desks cost but little more than ordinary ones. One matter of great importance is a hospital room for the reception of teacher or scholar who may be taken suddenly ill. In addition the teacher should be taught how to use such a room. Desks and floors are rarely washed. They need it at frequent intervals to keep them in a proper condition. He had known instances where this was neglected for nearly a year.

GOVERNMENT METHODS FOR PREVENTING THE POLLUTION OF STREAMS.

by C. P. BASSETT, C. E., of Newark. He said: Streams are polluted and forests are destroyed at the will of those who please. All common sense shows this must be prevented, but how? Every one insists that the stream at his own door must be pure, but cares little in what condition it is when it leaves his vicinity. Voluntarily, they never attend to this vital matter. We must have laws to prevent this. We certainly have laws, but their enforcement demands too much litigation, with no one to do the work. There should be supervising authority, such as the River Pollution Commission in England, which has done much good work. These have power to investigate and put a stop to all pollution. In this country, factories and houses are preferably erected on the banks of a stream that may serve as a conduit to carry off the filthy products they care not where. Stream pollution is cumulative: it gathers as it runs. A proper board or commission could regulate such factories when being built, and not wait until they are completed and then become nuisances. Massachusetts has the best results because of her law which requires the State Board of Health to take charge of the streams and can say to the community, you can do so and so, but not what may render this stream foul, whether for drinking or other use. This law is a good model for the other States. There is a crying need for it in New Jersey. In the discussion, which was quite general, the very foul condition of the Passaic River was especially noted, as it supplies several places besides Jersey City. Dr. Mortimer Lampson of that place graphically detailed the supply of filth which was offered the people of that important city as a drink.

PERRY JACKSON, Esq., of Beebeville, a small place on this river opposite to Jersey City, portrayed the condition of the river as it flows past. Laws were plenty, but all require that it shall be shown to be a nuisance, and by whose action, hence preventing action in the premises. Streams are everywhere regarded as natural sewers to carry away the filth of the cities or towns which grow up on their banks.

This paper

ARTESIAN SOURCES OF PUBLIC WATER SUPPLIES IN NEW JERSEY,

in the absence of its author, J. C. SMOCK, Ph.D., State Geologist, was read by DR. A. W. STRICKLER. He outlined this very interesting and valuable paper, as follows: There are no reservoirs or subterranean pools so much talked of. Seams, joints, strata, fissures in the rocks or places filled with loose earth act as water-ways. Some earths are saturated with water and it is from thence comes the supply to the borings. The deeper we get the greater extent of water-bearing strata, and hence the greater and more constant the flow. Before a boring is made, careful examination is needed as to the geological formation, that our efforts may meet with success. Some waters are mineral because the water in its course meets soluble earths, from which we have iron, alkaline or other springs. Pollution of artesian wells is the result of the drainage into them of filth from the surface. The future of artesian wells is a great one. They will eventually be the source of the drinking water of this State.

A discussion followed in which Professor Lewis Woolman of

Philadelphia exhibited a series of diagrams showing the strata and the wells of the State.

DR. THOMAS K. REED, ex-Mayor of the city said the best way to get good drinking water was by this method. Surface water should never be used. Malarial disease in all its forms comes from the use of surface water. Deep-seated water ensures the absence of this trouble.

It should be named mal-aqua, not malaria. At the depth of 150 feet no organic life can exist, hence these waters are exempt from these impurities which engender disease. Eighty per cent. of our frame is water, hence we are all sponges, and we should be sure that that proportion should be the purest we can obtain. He objected to the name "artesian," they should rather be called "deep wells."

On motion of DR. HENRY MITCHELL, Secretary of the State Board of Health, the following was adopted.

WHEREAS, An order of the United States Post-Office Department provides that the mails shall not be used for the transmission of diseased tissue; and

WHEREAS, Specimens for bacteriologic examination, when inclosed in proper packages, can be transported in the mails without endangering the health of persons who may handle them; and

WHEREAS, Bacteriologic examinations in cases of diphtheria and other infectious diseases constitute an invaluable defense against the spread of communicable diseases by providing an exact method for early and accurate diagnosis; be it

Resolved, That the New Jersey State Sanitary Association hereby respectfully requests the Postmaster General to so modify the order now in force that specimens of diseased tissue, when properly inclosed in approved mailing packages, may be transmitted to state and municipal authorities.

DR. MITCHELL explained that such packages had been tested in many ways: crushed beneath a railway car, smashed beneath a heavy hammer, etc., without a particle of fluid escaping.

State committees on legislation and on sanitation were appointed by the president.

M. N. BAKER, C.E., of Montclair, read a paper on

PURIFICATION OF WATER SUPPLIES BY FILTRATION.

Few of the 2,500 water supplies in the United States are free from sewage. Strange how people prefer to drink their own filthy discharges! To free waters thus fouled the easiest plan is filtration. The ordinary sand-bed requires too large areas. The real danger is from bacteria. These must be removed. Mechanical filters clear the water of bad taste and odor and color. Filter beds are successfully used to remove iron, coloring matter and bacteria. The Massachusetts State Board of Health have the best opportunities to test this, as they have an appropriation annually of \$25,000 for this work. Their experience has been with filter beds or tanks, the result being tested by chemists and bacteriologists. An objection was the slowness, but it was found that the water could be forced through at twice the rate with equally good results. There are no true filters in New Jersey. Mechanical filters are not favored by the Massachusetts State Board. We have some filters in the State which are used for special work, as the removal of iron or other matters.

DR. JAMES A. EXTON, of Arlington, read a paper entitled

IMPROVEMENT OF THE LOCAL ADMINISTRATION OF TOWNSHIPS.

A uniform method of administration is much needed. Contagious and infectious diseases are not opposed as they should be. This opposition should be equal to that against law-breakers. Local boards are apt to antagonize, and the State board alone can harmonize them. Again, training in the work is required, as in very many instances the members and officers of the local boards are not so educated as to know what to do in certain cases. He had addressed queries to the local boards in Connecticut, where the best law existed for local boards, and he quoted from 1,000 replies. They have less expense and better results. The new law recently adopted there was quoted as being the best form in such cases. It is explicit and easy of enforcement. He urged it as a model for New Jersey to adopt. It would require only a few changes. He would place the appointment of all health officers in the hands of the civil service authorities and thus secure the very best talent.

PROF. C. C. BRACKETT, M.D., of Princeton, said: We must make board of health work a business, and carry it on with business principles. It pays well as a good investment. We should act as the manufacturers do, they select the best employees possible: so must we, and get the best talent to be found in the State. The inefficient fear to act lest they interfere with friends. Although there is a physician on the board, he often appears to see no need of action: there are no meetings, no plans; finally the matter falls into abeyance. But the manufacturer attends to it that the work is done and done

properly, and the valuable results are shown by his book. We must have better material in the boards: if necessary put them under an examination and only take those who are fit to do the work. Particularly should the doctor be examined as to his knowledge of sanitary science, and all others as to their knowledge of the laws which should apply to these cases. The boards should keep records of the whole place; thus they are able to know the cause of a disease owing to the presence of improper drainage, etc. At present there is no inducement for proper men to accept these places, as they are liable to be dropped for want of political influence or the like. Again, they are not paid enough to induce them to work. They should be kept in office during good behavior and while they do their duty. What costs nothing is worth nothing: we pay good servants well and obtain good service. When we secure these we will find excellent results.

DR. ENGLISH (the president) took the same ground. Improve the officers. Good roads are regarded as of more importance than health. Health men should always be students of sanitary science and of the laws which apply to the enforcement of what is needed for the work: they should carry out the suggestions of the State board, and feel responsible for an infectious disease that may break out in their locality. Bad roads must pay for the damage which takes place to a wagon or to a horse, but the board of health does not think of preventing disease. We must improve the people in sanitary ideas: let them know the great need of pure food, pure water, the value of quarantine: then we will have their coöperation, and this becomes the special duty of the health officers to do to the best of their power. Circulars should show the value of isolation in the prevention of the spread of disease. When disease prevails the sanitary code should be ready to stand the test of the law, the physicians should be compelled to report the cases, the houses placarded.

On motion of DR. H. MITCHELL the whole matter was referred to a committee of three to report a plan for the proper organization of the local boards.

DR. R. MEADE BOLTON, Chief of the Bacteriologic Department of Philadelphia, read a paper on

DIAGNOSIS BY BACTERIOLOGY.

He said all were not fit to be bacteriologists. They should be selected for their knowledge and experience. He had taught many, but in spite of every effort, they were not fitted for the work. It is not easy in every instance to recognize bacilli. Additional experiments are often needed to perfect the diagnosis. Animal experiments must be brought to our aid. Water examination is generally for typhoid and cholera. Here often doubt exists. Thus with cholera, other bacilli resemble the comma bacillus, and only by control experiments can we obtain the proof. An immunized guinea pig is inoculated, true comma bacilli at once die: they can not increase in number; but the similar form rapidly increases. Soil examination is needed for the agriculturist lest germs exist which may prove injurious to the cattle. The air is not loaded with microbes as was once taught: they sink to the floor and are only stirred up by the movements of people. It is not always possible to know the bacilli of typhoid fever. Still, bacteriology has been found of great value in special cases. There still exists some doubt as to there being a special bacillus of typhoid fever. In diphtheria this science proves of great value. We may diagnose the disease early, even before clinic symptoms show themselves. In cholera this has often been done, the germs being found in the feces though no diarrhea existed, and this will account for the occurrence of sporadic cases or outbreaks. Prompt diagnosis here is of great value: such cases should be isolated. This is a hardship, but it is necessary. In one instance a gentleman and his family were kept at home until they were known to be clear of the disease. So with diphtheria, the throat may show the presence of the danger, and it is hard to say what is best to do.

DR. MITCHELL said that this State was just ready to begin this work. The building is ready, good men have been secured and in a few days work will begin. He would issue a circular of information to all.

Plumbing inspection occasioned much discussion. Samples of bad work in this line were exhibited, and in the remarks of practical plumbers present these were condemned as the work of unskilled men or the result of efforts to put all the money on the outside of the house, without attending to the more important sanitary matters. The need of selected men who knew their business and felt responsible for their work was shown. Plumbers often oppose the assumption of authority by the health board: a conflict is now imminent and they as a body are proposing to have their own people appointed. It will be better to have examinations made by practical men, and pre-

ferably by those who are posted in sanitary matters connected with this business.

A resolution to that effect was unanimously adopted.

The disposal of garbage was then treated of by W. G. HOOPES, of the Atlantic City Health Board. He showed that they were able to cope with the question for eight or nine months in the year, but when the immense influx of visitors came to the shore, as they do in the summer months, then more aid is needed, and during the past year it was found that additional furnaces were required to consume it. The plant was a furnace which consumed its own gas after starting, and did the work well. Cremation was the only way to get rid of the stuff. His explanation was extremely interesting, but space will not permit of a detail.

DR. W. C. R. COLQUHOUN, health officer of Wilmington, explained the method adopted at that place. It was similar to that used at Atlantic City, and was only adopted after very careful inquiry and rigid tests. A steel furnace was employed.

On motion of Dr. Leal a resolution was adopted urging upon the Legislature action relative to the Passaic River to relieve it of its present foul condition.

The officers elected for the ensuing year were: President, Shippen Wallace, C.E., of Burlington; vice-presidents, James Owen, C.E., of Montclair; J. C. Smock, Ph.D., of Trenton (State Geologist); V. L. Davey, East Orange; recording secretary, James A. Exton, M.D., of Arlington; corresponding secretary, J. M. Watson, of Elizabeth; treasurer, George W. Howell, C.E., of Morristown.

A satisfactory balance was shown in the treasury, and it is contemplated to issue the proceedings in pamphlet form. The executive committee will decide as to the place of meeting for next December.

NECROLOGY.

RICHARD L. VAN KLEECK, M. D., of Brooklyn, died December 18, of paralysis, aged 56 years, a cerebral hemorrhage having occurred six days previously. No man in the town of Gravesend was more universally beloved than Dr. Van Kleeck. He was a leading physician in general practice. Dr. Van Kleeck was born in the town of Berne, Albany County, in 1839, and at 4 years of age he moved to Flatbush with his parents, his father being the first rector of St. Paul's Church at that place. He entered New York University, and received the degree of M.D. in 1862. After a year's service as interne in the Kings County Hospital, he began private practice in the town of Gravesend. His public positions were those of health officer and postmaster, which he held for twenty years or more. Dr. Van Kleeck was married over a quarter of a century, and his wife survives him together with his two sisters. He was of a hearty, cheery disposition; sometimes outspoken and fatherly in his advice, but always kind hearted.

DANIEL AMBROSE, M.D., formerly of Brooklyn, died in London, England, on December 16, in his fifty-third year. At the time of his death he was a M. P. of the anti-Parnellite party for the South Louth constituency, Ireland. He left Brooklyn about ten years ago, and in 1892 and 1895 secured his elections. His death is ascribed to cardiac disease. A widow and a family of nine survive, of whom the eldest son will presently go up for his medical examinations in London. Dr. Ambrose was born Nov. 14, 1843, in the County of Limerick, Ireland, his family being a race of doctors. His brother, Dr. J. K. Ambrose, was coroner of Richmond County, New York, in 1883. Dr. Daniel Ambrose received a preparatory education in Ireland and at the age of seventeen took up the study of medicine in the hospitals and schools of Dublin. In 1864 he received a diploma of a licentiate of the royal College of Surgeons in Ireland, and was made a doctor in medicine of the Queen's University in 1865. During that year he went to Brooklyn and took up his residence there and remained for a period of twenty years. In 1886 he joined the Kings County Medical Society, and was connected with St. Mary's Hospital at its inception. In 1875 the Charities Commissioners of Kings County appointed Dr. Ambrose physician to the department. In 1879, on account of ill health, he abandoned practice for a time, and a business opportunity to his liking offering itself, he accepted it, and became a man of affairs, and large ones at that, from that time onward.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 86 FIFTH AVENUE, CHICAGO, ILLINOIS.
W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, JANUARY 4, 1896.

NAVAL REORGANIZATION AS IT ESPECIALLY CONCERNS THE MEDICAL PROFESSION.

The imminence of international complications, compelling Congress to reorganize the military establishment to be as effective as possible, makes that portion of the report of the Chief of the Bureau of Medicine and Surgery of the War Department which accompanied the annual report of the Secretary of the Navy, relating to the persistent vacancies in the medical corps of the Navy, of especial interest to the general professional reader.

The Surgeon-General says:

During the last fiscal year there were 269 applications made to the department for information concerning the appointment of assistant surgeons in the Navy. Replies containing instructions were promptly forwarded in every instance. Out of this number *only 33* applied for permission to appear before the Naval Medical Examining Board, as follows:

Alabama	1	New York	8
California	3	North Dakota	1
District of Columbia	1	Ohio	1
Illinois	1	Pennsylvania	1
Kentucky	1	South Carolina	1
Massachusetts	3	Tennessee	2
Michigan	1	Virginia	2
Mississippi	3	West Virginia	1
New Hampshire	1		
New Jersey	1	Total	33

Of the 33 mentioned who received permission 19 availed themselves of the opportunity to appear before the Board, and of this number there were 3 rejected physically and 12 rejected professionally, leaving *only 4 out of the 269 original applicants*, representing every section of the country, who were found qualified for appointment as assistant surgeon, viz.:

Alabama	1	California	1
District of Columbia	1	New York	1

It may be well to mention, for comparison, that there is no difficulty in filling vacancies in the medical corps of the Army and Marine-Hospital Service, both corps having at present the full quota of assistant surgeons allowed by law, while at this date there are *fourteen* vacancies in that grade in the medical corps of the Navy, and the services of that number of assistant surgeons are needed at once for hospitals, ships and other stations. The law does not provide for the temporary appointment of acting assistant surgeons to meet the emergency that has arisen.

In our issue of December 14 we alluded to the reasons for the disinclination of young graduates to enter the naval medical service because of the inferior pay and status of the naval medical officer compared with those of medical officers in the army. The figures of the Surgeon-General are significant. It is absurd to suppose that among the hundreds of graduates of old schools as Harvard, the College of Physicians and Surgeons of New York, the University of Pennsylvania, Ann Arbor, our own Chicago schools and others, there are not to be found *fourteen* able to pass the examination for admission into the navy. Indeed, the members of the Naval Medical Board of Examiners have over and over declared that their examination is only such as any properly educated young physician should be qualified to pass without special preparation. It is just as absurd to believe that among these graduates there are not *fourteen* young men to whom the prospect of an assured income from the start is not an inducement. The only possible inference, and one that is highly creditable, is that there are not *fourteen* young physicians in the country who do not hold the honor of their profession so high that they refuse to enter a service where they will be subjected to indignities to which the possessor of a diploma should not be subjected, and so long as this is the case the Army and Marine-Hospital Service will continue to attract the eligible graduates, notwithstanding the allurements of foreign travel on board a man-of-war.

We have already indicated the remedy for this state of things in the elevation of the naval medical officer's position to the level of that of his army colleague, for which the time is opportune. The engineer corps of the navy has taken the lead in framing a bill for its reorganization, made necessary by the changed conditions of the new navy. The days of the reefer—when tacking and wearing were the nautical problems—when steam power was auxiliary and the engineers a tolerated body of despised mechanics—are no longer. The modern man-of-war is a complex machine, which only skilled mechanics of the highest order of attainments can control, and the engineer corps has wisely considered only its own special needs. The medical corps should do the same. There is no reason why the number of medical officers and their requital should be graded by the number and pay of paymasters, engineers and chaplains. Within the lives of the older officers, the medical corps once occupied an independent and distinctive position. The surgeon-of-the-fleet had no parallel. The absurd imitative titles of pay director and pay inspector were created to offset medical directors and medical inspectors. The young medical officer was a ward-room officer from the start. Now he begins his naval career only as an ensign in the steerage, the messmate and associate of

undergraduates from the naval academy. The identity of the medical officer is sunk under the generic designation of the *staff*—with engineers, paymasters, chaplains, constructors, professors of mathematics and civil engineers, notwithstanding the fact that the medical department of the United States navy is contemporary with the creation of a naval force, which first appears on the statutes by act of Congress, approved March 27, 1794, and is consequently, with the line, the oldest of the coördinate branches of the naval service. To restore the medical corps to its former prestige no lower professional standard of pay and position will be equitable and acceptable than that existing in the army to-day. It is absurd that two young graduates shall enter—one the army and the other the navy—after a precisely similar ordeal of examination, to perform precisely the same character of duties, with equal responsibilities and obligations, but with such an enormous disparity of rank and reward as exists between the two services.

We are glad that the *Association of Military Surgeons of the United States* has determined to advocate the cause of its naval associates. The resolution of GEN. J. D. GRIFFITH, of Kansas City, late Surgeon-General of the State of Missouri, looking to the equalization of the medical corps of the two services, commends itself to every physician in the country and we hope they will make themselves heard through their Senators and Representatives in the Congress now in session, when the subject of the general reorganization of the navy shall be considered, and that not only the existing fourteen vacancies may be speedily filled by the flower of the profession, but, as was the case fifty years ago, there may be nearly twice as many acceptable candidates examined and approved in expectation of possible vacancies.

A VALUABLE WORK.

Much information of value is yearly consigned to oblivion by publication in the voluminous annual reports of the various heads of bureaus, chiefs of divisions, etc., at Washington. Volumes issue from the Government printing office by the ton of whose mere existence the mass of the people never become aware. How many of the sixty-odd thousand physicians of the United States have ever seen a copy of the Annual Report of the Chief of the Weather Bureau (late Signal Service)? Some few perhaps have looked over individual reports, and have been impressed with the variety and value of the climatology data being thus slowly accumulated. But they have felt that, however interesting and suggestive the report of a year's observations may be, yet in the nature of things it is by itself of no practical value. For it is only by combining the data for any given point for some five years that they become an index, even then unreliable, of the normal climatic condi-

tions there found. The data for ten years, however, when worked up, are of great practical value; and from the data for twenty years may be deduced with almost perfect accuracy the normal characters of any given climate.

If there be few medical men who have ever seen an ordinary Annual Report of the Weather Bureau, there are fewer still who know that in Vol. I of the report for 1885 there is a series of tables of great value, compiled, as a rule, from all observations from the date of the establishment of the various stations up to 1885. They embrace nearly every feature necessary to an exact and comprehensive knowledge of every element that goes to constitute climate. No physician can study these tables without an appreciation of the extent of his previous ignorance of the climatology of the United States, and without a deep sense of their great value. At that time, however, (in 1885) many of the stations were but recently established, and consequently the data at those points were insufficient. Ten years have now elapsed and should these tables be now brought up to date and published, they would form a volume of great and permanent value, which should be found as a reference manual in the library of every physician in this country.

Some of the tables in the work referred to might be omitted or modified, and other tables might be added. Also, some information about the physical and geological features of the country around the various stations might be appended, and the nature and sources of the water-supply, the natural drainage, vicinity of mineral springs, etc., might be briefly indicated. But, brought up to date even in its present lines, this volume of tables would be of immense practical value, not only to physicians and health-seekers, but, in an economic sense, to the agricultural and horticultural interests, as well as others. It would be a laborious task; but when it is considered that, apart from the daily use made of these observations to forecast the weather, their permanent value depends altogether upon their tabulation as above indicated, it would seem entirely reasonable and proper to ask that the work be done without further delay.

For the present, however, we can only advise those physicians who have not the existing volume to obtain it if they can, for so long as change of climate is to be intelligently prescribed it will prove invaluable. We can not mention all the tables, but will briefly indicate a few, in order that their scope and value may be apparent. These tables show, for each station: Mean normal pressure, by month and year; highest and lowest pressures; mean temperatures, by month and year; mean daily range of temperature; highest temperatures recorded, by month and year; lowest ditto; monthly maxima and minima; mean

temperature at 7 A. M., 11 A. M., and 3 P. M.; mean A. M., P. M., and midnight temperatures: monthly and annual precipitation; mean relative humidity, by month and year; dewpoint, by month and year; dates of first light and first killing frost; dates of last ditto; direction of winds, by month and year; average hourly velocity of winds, by month and year; average cloudiness (scale of 0 to 10), by month and year; average number of clear, fair and cloudy days.

These are some of the more important of the seventy-one tables of this great compilation. The editor of this JOURNAL was one of those who submitted plans for the extension of the work of the weather service into the medico-climatologic field, and naturally we are interested in seeing the successful accomplishment of this work.

LATENCY OF INFECTION AND DISEASE.

An interesting discussion that was continued through two meetings of the Royal Medical and Chirurgical Society of London, brought out some interesting points as regards the so-called latency of certain germ diseases. The participants in the discussion included, among others, such men as JONATHAN HUTCHINSON, DR. P. MANSON, J. ERNEST LANE, SIR W. BROADBENT, which fact it lends a certain importance as expressing up-to-date English opinion on the subject.

Latency, in the sense of the term as used in the discussion, implies the possibility of a disease germ lying quiescent for a longer or shorter period after its introduction instead of at once showing its virulency in the usual way, and the microbes of hydrophobia, syphilis, tuberculosis and leprosy were referred to as affording instances of this phenomenon. The matter is an important one, for as MR. HUTCHINSON stated, it has a very important bearing on some questions of infection; what is often attributed to lack of care may really be only the result of stirring up the soil containing these latent germs. It thus adds, or rather it makes us conscious of a new surgical danger, and one that no precautions can insure against. It is often impossible to say when any germ, except a very few specially inoculated ones, enters the system, and it is probable that we have many of them constantly with us, and among these more especially may be mentioned the ordinary pyogenic microbes and those of pneumonia, tubercle and diphtheria. These lacking the special soil for their development are harmless, but when some disturbance of the health or some accident occurs, as in a case reported by SIR W. BROADBENT, where a young man developed tuberculosis after a fall from a horse, they then take on their activity and produce their morbid symptoms. The germs may be encapsulated and thus released or some other disorder of the system, itself infectious or otherwise, may call out their activity.

Properly speaking, as pointed out by HUTCHINSON, true latency requires that there be no vital activity of germs and we can not therefore include a large proportion of the apparently latent cases of syphilis and probably also of tuberculosis as really falling under this head. His illustration of a field in which the seeds of poppies had lain absolutely quiescent for eight years and had then grown, is an apt one to show what is meant by true latency. Latent bacteria must be either encysted or surrounded by resistant tissues, and perhaps the most striking pathologic example in the human subject is afforded by leprosy, the infection of which it seems may be incurred in a region where it is endemic, and the disorder only appear after many years' residence in a country where it does not normally occur and where a reinfection would seem to be practically impossible. Another, which may perhaps be questioned by some, is that of hydrophobia, the mode of infection of which is altogether special and impossible to occur without the knowledge of the subject, and which has been reported as lying latent for months and years in the system. The diseases, the germs of which are liable to be always with us and from which infection may occur at any time unconsciously, such as tuberculosis, erysipelas, diphtheria, etc., can hardly serve as well as typical examples of latency, though it would be impossible to absolutely exclude it, and their relations to the subject are therefore practically just as important. It matters little, in fact, whether infectious germs are encysted in resistant tissue in an organism that is generally their prey or whether for special reasons that organism is at the time generally resistant as far as the possible breaking up of this resistance by disease or accident is concerned, but it is a very important fact to know that we may by a single exposure create the possibility of an outbreak of disease at some indefinite future time.

There is as was pointed out in the discussion, a possible distinction to be made between latency of the disease and latency of the germ, and it is probable that either condition may exist. A disorder apparently cured may be only latent, as is tuberculosis or syphilis, but the late appearing leprosy and hydrophobia are better explained by the hypothesis that the germ only had been introduced and had been lying quiescent in the system till for some reason or other it was aroused to activity. This would meet the condition of true latency as defined by HUTCHINSON better than would arrest or latency of a disease that had once developed its morbid symptoms; but, as already inferred, the difference is not one of great practical importance. The really important fact, as it seems to be a fact, is that either germs or their products can undergo an arrest in their development or progress that is not actual extinction, and may be again revived to all their original and natural viru-

lency. Our present knowledge of the subject is much more in the suggestive than in the positive stage, but the practical bearings of even the suggestions are almost infinite.

A BASE SORT OF CHRISTMAS STORY.

The president of a prominent life insurance company has contributed to one of our weeklies a "Christmas story," the turning-point of which is made to be the abominable rascality of a young medical examiner to a life insurance company. The scene is laid in Cumberland, Penn., and the rascally young doctor is named VAN DOREN. The crime alleged in the tale—and it is "founded on fact," according to the writer—was the return to the company of a false report on a certain application, for the purpose of intriguing his rival, a young lawyer, out of a matrimonial engagement. The villainous trick works to charm until the last moment, when the scamp becomes conveniently intoxicated, and reveals the fact of his false report and a long chain of disasters to his rival, so that the rival is saved from despair and an untimely grave.

This gross and horribly improbable story has been gotten up for a Christmas story, forsooth, by a man whose business for years has been largely dependent upon the painstaking and truthful work of his company's medical examiners. We do not envy the writer of the story the average current and movement of his mind during his leisure hours, if his inventive faculty can not frame for itself any purer fancies than this that he has given to the public. The story is one that is likely to rebound and create a feeling of detestation against its author in the minds of all the medical men who have anything to do with his company, and he may before long have occasion to regret that his imagination played him so sorry a trick. We are entirely incredulous as to the foundation on fact that is claimed by the writer. If he thinks he has the facts, we believe that he has been hoodwinked, and that his informants have an axe to grind. There is a certain amount of "the horrible example" about the medical wretch of the story, for we are told that he was also intemperate and a bar-room roysterer, who shortly after the exposure of his plot drank himself to death. Perhaps the story has been drawn up to scare some of the author's young medical examiners away from the demon of alcohol. This is the way the narrative is closed:

"The President of the life insurance was very much concerned as to what he ought to do about DR. VAN DOREN. He was immediately dismissed; *cela va sans dire*. But after consulting counsel—and the President was a little bit of a lawyer himself—he couldn't exactly see how the offender could be brought to bar. Fortunately, he (the President) drank him-

self to death in a short space; policy forfeited for non-payment of premium. His rival is still living, with a heart for any fate, and the holder of the limit in, let us say, the *Greatenormous* Life Insurance Company. The story has no moral; it has not even the usual tag—Insure in the *Greatenormous* Life Company."

We are agreed, The story has no moral. It is even devoid of morality, in its implied confiscation of the fair name of medical examiners. In this Christmas season good is to be returned for evil; not evil for evil; much less evil for good.

THE MEDICAL AND SURGICAL HISTORY OF THE WAR OF THE REBELLION.

Several Medical Societies have recently petitioned Congress to reprint the six quarto volumes of the Medical History of the War. The reprinting of this great work would indeed be desirable, but we would like to see the illustrated catalog of the Army Medical Museum printed first. The former publication being in all our large libraries is already accessible to a great many, but the immense collection of specimens illustrating anatomy, histology, pathology and military surgery, is only accessible to gentlemen residing in Washington, or visiting the capital, and the reproduction of this collection in book form would be of the highest educational value.

The publication of a carefully compiled critical review of the medical and surgical records of the Pension Office, showing the subsequent history of the vast numbers of wounded and disabled soldiers, would also be of great utility to the entire profession. The generosity of Congress has been frequently shown in many directions, but here is one that would furnish information of the highest practical value to the country.

BRITISH MEDICAL ASSOCIATION.

The *British Medical Journal* in its issue of Dec. 21, 1895, publishes a list of the members of the Association, from which it appears that the membership of that body has now reached 18,100. This shows what systematic organization can accomplish. Let our members signalize the year 1896 by bringing our membership up to 12,000. One new member by each member will do it. This done, we may surpass any other in 1897. We have great reason to be pleased with the steady increase in the membership list, and it shows that our members are taking hold in earnest, but "be not wearied in well doing." Let there be no rest until all regular practitioners are organized under the ASSOCIATION for the general welfare of the profession.

HONOR TO DR. DRAKE. It is suggested that the name of Dr. Daniel Drake be perpetuated by the erection of a monument in Cincinnati; or, that the new medical department to be established by the University of Cincinnati, be designated the Drake Medical College. *Medical Bulletin*.

CORRESPONDENCE.

The International Scientific Language.

CHICAGO, Dec. 23, 1895.

To the Editor:—I was very much pleased with your article in the last number of the JOURNAL on "The International Scientific Language," and I think that in the main I agree with you. But I feel sure that you did not lay sufficient stress upon the unfortunate fact that the ability to speak French is quite a different thing from the translating knowledge. The former is rarely acquired after a certain age and almost never outside of a French school or a French-speaking locality. For instance, the only French that I heard spoken by Americans at the Pan-American Medical Congress—with one or two notable exceptions—was of that variety which Chaucer designated as of "Stratford-atte-Bow," and it was excessively painful to listen to. When the time comes that a man will commence to prepare himself for the study and practice of medicine at 12 years of age,—as you know is often done abroad the acquisition of conversational French will form part of his preliminary education, but as things now are, the ability to *translate* technical articles is about as much as one medical man out of a hundred will be likely to acquire.

But this is not what I set out to speak about. I should feel obliged if you could tell me where I can procure Kostomoir's Greek work, "On Ophthalmology and Otology of the Ancient Greeks." I have not much intention of translating it, but I wish it for reference and for my library.

Very sincerely yours, CASEY A. WOOD, M.D.

CLEVELAND, Dec. 30, 1895.

To the Editor:—I read with much interest your address on "The International Scientific Language," and heartily indorse what you said. Especially am I in accord with your ideas of the practicability of French as against the sentimentality associated with the Greek language. I sincerely hope that you will continue to use your influence to have French indorsed as the international language. Very truly yours,

WILLIAM E. WIRT, M.D.

A Typographic Error.

MUSCATINE, IOWA, Dec. 24, 1895.

To the Editor:—As I was reading an article in the issue of December 21, p. 1090 of the JOURNAL, I came across this word, "tribaism," in second column, line 41. I could not find its meaning from any books at my command nor from any of my "Roman friends." I am yours fraternally,

ELLIOTT R. KING, M.D.

ANSWER:—The word was misprinted by the omission of the letter "d." It should have been printed *tribadism*.

BOOK NOTICES.

Injuries and Diseases of the Genital and Urinary Organs. By HENRY MORRIS, M.A., M.B. Lond., F.R.C.S. Svo. cl. pp. 478. with ninety-seven illustrations. New York: William Wood & Co. 1895.

This is an excellent monograph, quite up to date, with many special illustrations. The diseases and injuries of the scrotum, testicles, vesiculæ seminales, penis, urethra, prostate and bladder are treated of in the book. The author's advice, based as it is on large experience, is sound and trustworthy. In the matter of style, there is some ground for criticism, but as its teaching is in accord with modern views on the subject, little need be said. The book like many others, might be easily pruned, so that a loss of 5 per cent. of its superfluous words, would add to its clearness. These are usually Britishisms. "The poor fellow described them as being like to round clear

bladders or berries," p. 264. "And was thereby able to suture the cut edges of the floor *together* around a No. 8 catheter," p. 265. "The pus burrowed *up* through the pelvis, etc.," p. 265. "The average time from *start to finish* is from three to nine months," p. 323. "One feels that the rectum is close *up* to the posterior surface, etc.," p. 333. "Nothing but a layer of cellular tissue, and *not always* that separates," p. 333. "If these means afford positive signs, *well and good*; but if not, we must not exclude," p. 440. Barring this peculiarity, the book is to be commended for its practical value, and its sound common sense.

An American Text-book of Surgery, for Practitioners and Students by various authors. Edited by WILLIAM W. KEEN, M.D., LL.D., and J. WILLIAM WHITE, M.D., PH.D. Second edition, carefully revised. Royal octavo, cl. pp. 1248. Philadelphia: 1895. W. B. SAUNDERS. For sale by subscription. Price \$7.00.

Seven professors of surgery: two hospital surgeons, and one professor of ophthalmology have modestly consented to anonymously assist the responsible editors in the production of this well-known and deservedly popular text-book.

The chief criticism directed against the first edition, was that it was unequal in the relative importance given the various topics, that certain unusual operations were enlarged upon by essayists to the exclusion of other more common topics of everyday interest to the young practitioner. This criticism has been met in this edition by many additions that will materially increase the value of the book. The alterations have made only slight increase in the number of pages. Additions to surgical knowledge follow one another with such rapidity that while the pages of a text-book are still fresh from the press, omissions begin to be noticed. The additions in present volume include a section on acromegaly, a chapter on symphyseotomy, statements concerning the effect of modern small arms in military surgery, the Murphy button, the Hartley-Krause method of Gasserian ganglion removal, Schede's operation of rib resection, and many minor changes. That the book has improved there is no question, and we have no doubt the third edition will be called for in about the same time that has elapsed since the appearance of the first.

A Manual of the Practice of Medicine. By GEORGE ROE LOCKWOOD, M.D. Illustrated. Svo. cl. pp. 935. Philadelphia: W. B. Saunders. 1896. Price, \$2.50.

The author says that it has been his aim "to present in this manual the essential facts and principles of the practice of medicine in a concise and available form."

It must be conceded that he has fairly succeeded, but in our judgment much condensation can still be done with advantage. A sample of unnecessary verbiage may be seen on p. 263 where the author says: "By such exercise the really weak heart *goes to pieces*, while the healthy neurotic heart *clears up*."

It would be extremely interesting to have the author inform us of the exact pathologic change which occurs in the heart when it "goes to pieces," by any kind of exercise, or when being "neurotic" it "clears up."

Many a good book is spoiled because its author is careless in the use of words. In these days when there are so many excellent works on nearly every conceivable subject, every superfluous word inflicts unnecessary toil upon the reader. The old system of dosage is used.

NEW INSTRUMENTS.

NASO-PHARYNGEAL BLADES AND UNIVERSAL HANDLES.

BY J. E. SCHADLE, M.D.

ST. PAUL, MINN.

This instrument has many advantages other than its "*en plus minus*" construction, which is, perhaps, the first thing that appeals to one upon inspecting it. By means of the ball

and socket joint, effected by the union of the different blades with the holder, the operator is enabled to fix his instrument at any angle he desires to fit the exigencies of the case presenting, and to hold it perfectly firm—as firm as a needle is held in a Hagedorn needle-holder. The handle is made sufficiently heavy to have it balanced well, and to be of utility in cutting where force is required in a small space.

Inasmuch as many of these blades are new, I would like to describe them briefly so that they may be better understood. The first and second blades (see cut farthest to right and immediately over the handle) are designed to be used in making caustic or alternative applications to the base of the tongue in the treatment of enlarged blood vessels or masses of lymphoid tissue. No. 1 serves an especially good purpose in such work for the reason that the remedy can be accurately applied and the epiglottis can, at the same time, be thoroughly protected. It is a small metallic, shovel-shaped officer with a smooth back, into the upper surface of which is inserted a rectangular piece of metal full of small perforations, not unlike a cullender. No. 2 is on the same principle but much smaller and of circular form, adapted more particularly to the cauterization of small points. No. 3 is a saw particularly adapted to the breaking up of adhesions between the soft palate and the posterior wall of the pharynx. No. 4 is a dissecting blade. Nos. 5 and 6 are sharp spear-pointed blades designed for exploring pus cavities, as in peritonsillar and tonsillar abscesses. Their use is invaluable, causing but little pain and enabling us to locate with perfect accuracy the site for the evacuating incision. No. 7 is a cup-shaped curette or scoop which can be used in clearing out tonsillar pockets or crypts of concretions and breaking down the diseased walls. Nos. 8 and 9 are curved probe-pointed blades which answer an admirable purpose in removing tonsillar shreds

the conference of representatives of the health departments of Illinois, Iowa and Missouri, which was held in Chicago last October, met in Springfield, Ill., December 20. Drs. Scott and Griffith, of the Illinois Board of Health, Dr. J. A. Scroggs, Secretary of the Iowa State Board of Medical Examiners, and Dr. Paquin, of the Missouri State Board of Health, were present. It had been suggested that the committee formulate a plan for the issuance of medical certificates which would be recognized in either of the three States, but this was not attempted and the committee confined its work to the preparation of a report regarding medical colleges, which will be presented at the next meeting of the three State boards. This report recommends that the boards shall recognize only such medical schools as have facilities for teaching all branches of medicine and are well equipped for the work. They must have laboratories and teach physiology, pathology, chemistry, bacteriology, microscopy and have clinical resources. For graduation the recognized colleges must require no less than four years of study and not less than three full courses of lectures of six months each.

Boards of Health to Control Burials. A law has been passed in New Hampshire which provides that boards of health in cities shall have charge of the granting of permits for the burial of the dead: and no interment, disinterment or removal from the city of any dead body of any human being, nor deposition thereof in any tomb or vault, shall be made without a permit from said board or their duly appointed agent, nor otherwise than in accordance with said permit. No such permit shall be issued until there has been delivered to the board a satisfactory written statement containing the facts required by Section 1 of Chapter 173 of the Public Statutes, together with the cer-

or masses remaining after tonsillotomies. They are also of use in severing adhesion bands sometimes found existing between the Eustachian cushion and the vault of the naso-pharynx.

No. 13, like No. 4, is also a dissector and intended to be used in breaking down adhesions between the tonsil and faucial pillars.

The instrument has been constructed for me by George Tiemann & Co., of New York City. Mr. Tiemann will, I believe, be glad to show the handles and blades to any one who feels sufficient interest in it to call upon him.

PUBLIC HEALTH.

A Farm Colony for Epileptics in England. At Chalfont St. Peter, Buckinghamshire, a freehold farm to the extent of 135 acres has been given by Mr. Passmore Edwards to the National Society for the employment of epileptics. He has erected a home thereon, beside offering to build two others, one for boys and one for girls afflicted with epilepsy. There have already been some iron buildings occupied for over a year by eighteen patients, and the number of colonists has lately been increased to thirty six. Each inmate, if able, pays 10 shillings a week, and all are employed, chiefly in farm work, which is held to have a beneficial effect over the malady, inasmuch as the patients have fewer seizures so soon as they are actively employed.

To Regulate Medical Practice. The subcommittee appointed at

tificate of the attending physician as required by said chapter, or in absence thereof such other evidence as may be required by law. Upon the receipt of such statement and certificate the board shall forthwith countersign the same and transmit it to the city clerk for registration.

Public Baths in Brooklyn. Health Commissioner Emery sent to the mayor December 16 a communication in reference to the establishment of public baths, as proposed by an act of the legislature in 1895. This act provides that all cities of the first and second class shall establish and maintain such number of free public baths as the local board of health may determine to be necessary. Each bath shall be kept open not less than fourteen hours and be provided with hot and cold water. The erection and maintenance of river or ocean baths shall not be deemed a compliance with this law.

The public baths of Brooklyn now are river baths. Dr. Emery engaged the services of W. P. Gerhard, honorary consulting engineer of the health department, to assist in the formation of plans. He sent Mr. Gerhard's report to the mayor, together with plans for various styles and forms of bath buildings. The commissioner, recognizing the fact that the establishment of free public baths of this character will be in the line of an experiment, submits a design, calling for the construction of a one-story and basement building, wherein a separation of the sexes can be obtained and simultaneous baths afforded. The bath would cost probably not more than \$12,000 or \$15,000, exclusive of the land, and would provide baths for 450 persons a day. This building, said the commissioner,

can be constructed in such a manner as to permit the addition of a story, should the experiment prove to be satisfactory. In his opinion, a closely built up and densely populated portion of the city should be selected as a site. He thinks a suitable place can be found in the fifth ward, and that the maintenance would cost about \$10,000 a year.

Department of Public Health.—At a meeting of the North Texas Medical Association, at Greenville, Texas, the following preamble and resolutions were adopted:

WHEREAS, In the opinion of this Association, the condition of the United States demands a department of Public Health, under the control of a secretary, who should be a member of the Cabinet of the President of the United States, in the interest of the public welfare and the prosperity of our country, therefore be it

Resolved, That our members of Congress be urged to support the bill now pending and use their influence in securing its passage;

Resolved, That the secretary be requested to transmit to our Senators and each Representative in Congress a copy of this preamble and resolutions.

Resolved, That a copy of this preamble and resolutions be spread upon the minutes of this Association.

J. C. ERWIN, President.
R. D. POTTS, Secretary.

GREENVILLE, TEX., Dec. 11, 1895.

Typhoid Fever in Duluth. *To the Editor:*—The outbreak has been serious. The Health Officer reports that it is declining and that the profession are coöperating. I am now for more than a month making a series of analyses of the public water supply, both chemic and bacteriologic. We are leaving no known method untried to limit the disease or to discover the cause of the more than usual morbidity and mortality of the present outbreak.

Allowing water carriage all the influence it can be proved to have in distributing the specific cause of enteric fever, I believe the soil and other carriers are to a very considerable extent responsible and too frequently neglected.

Respectfully, CHARLES N. HEWITT, M.D.,
ST. PAUL, MINN., Dec. 27, 1895. Secretary.

A Board of Health Circular on Diphtheria.—The following is an extract from a circular of information issued December 15, to the medical profession of the city of Brooklyn, N. Y., regarding diphtherial antitoxin, the importance of isolation and hospital treatment. It is signed by Dr. Z. Taylor Emery, Commissioner of Health:

"Recognizing the fact that there is at the present time an unusual prevalence of diphtheria in this city, and realizing that measures instituted to limit its spread must receive the hearty coöperation of the medical profession in order to be effective, the Department of Health desires to call your attention to the following recommendations in the hope that they will meet your approval and enlist your active support.

"It is urged in every suspicious case of sore throat, especially when exposure to diphtheria is probable, a culture should be taken for bacterial examination so that a positive diagnosis may be made at the earliest possible date. Genuine cases of diphtheria may then be properly isolated and prevented from exposing others; while persons who have not the disease may be relieved from the necessity of such isolation and the children residing on the premises may be allowed to return to school. Before the patient is isolated it is advised that the carpet and all unnecessary furniture should be removed from the room, or, if it is not practicable to remove the carpet, that it should be covered with crash which should be kept in place until after proper disinfection of the apartment. In this way the removal of the carpet for subsequent disinfection may be avoided. As a result of every effort to limit the spread of diphtheria will depend chiefly upon the degree to which isolation can be carried out, it is urged that every case be isolated as thoroughly as possible, and that, with the exception of the nurse, all persons, especially children, be excluded from the room.

"The Department is prepared to furnish free of cost to any member of the profession who applies for it at this office, fresh anti-diphtheric serum of a high grade of antitoxic power, or condition that the full dose shall be given and that the blank

accompanying the bottle shall be filled out and returned to the Department. The use of antitoxin in Brooklyn having been as yet limited, your attention is called to the following figures from the Berlin authorities: Patients treated with antitoxin from Oct. 1, 1894, to April 1, 1895: Cases in private practice, 4,391; deaths, 349; mortality rate, 7.9 per cent.; hospital cases treated, 1,442; deaths, 210; mortality rate, 14.6 per cent.; total cases treated, 5,833; deaths, 559; mortality rate, 9.6 per cent.

"The great majority of cases of diphtheria occur in crowded tenements where proper supervision and isolation are impracticable or impossible. In such cases the Department urges the removal of the patients to the Board of Health Hospital, where they will receive the best of care, and where, if necessary, the mother or some other member of the family can go and remain as a nurse during the patient's illness."

Health Reports.—The following health reports have been received in the office of the Supervising Surgeon-General Marine-Hospital Service:

SMALLPOX—UNITED STATES.

Michigan: Detroit, Dec. 21 to 28, 3 cases, 1 death; Rochester, Dec. 21, smallpox reported.

SMALLPOX—FOREIGN.

London, Dec. 7 to 14, 1 death.
Dublin, Dec. 7 to 14, 1 case.
Glasgow, Dec. 7 to 14, 1 death.
Constantinople, Sept. 1 to 30, 10 deaths.
Buda-Pesth, Dec. 2 to 9, 2 cases.
Cardiff, Nov. 23 to Dec. 14, 1 case.
Madrid, Dec. 3 to 10, 5 deaths.
Montevideo, Nov. 2 to 16, 6 cases.
Nogales, Dec. 14 to 21, 2 cases.
Odessa, Nov. 23 to Dec. 7, 10 cases, 2 deaths.
Rotterdam, Dec. 7 to 14, 2 cases.

CHOLERA—FOREIGN.

Constantinople, Sept. 1 to 30, 18 deaths.
Bombay, Nov. 19 to 26, 6 deaths.
Calcutta, Nov. 10 to 17, 45 deaths.
Egypt, Nov. 27, to Dec. 5: Damietta, 18 cases, 19 deaths; Borachia, 9 cases, 10 deaths; Salamoun, 1 death; Farascoor and Siunomdij, 15 cases, 13 deaths; Zagazag, 3 cases, 2 deaths.

YELLOW FEVER—FOREIGN.

Cienfuego, Dec. 8 to 15, 2 deaths.
Sagua la Grande, Dec. 2 to 14, 20 cases.
Santiago de Cuba, Dec. 7 to 14, 29 deaths.

MISCELLANY.

To Preserve Health of Females. Every person, firm or corporation employing females in any manufacturing, mechanical or mercantile establishment in New Hampshire, it has been enacted, shall provide suitable seats for the use of the females so employed, and shall permit the use of such seats by them when they are necessarily engaged in the active duties for which they are employed. A fine of not less than \$10 nor more than \$30 for each offense is the penalty prescribed for a violation of this law.

The Legal Valuation of a Lost Limb or Member. In the case of James Roberts, a brakeman, against the New York, New Haven and Hartford Railroad Company, before Judge Lacombe in the United States court, the jury returned a verdict for the plaintiff for \$5,000. Roberts sued to recover \$50,000 damages for the loss of his right leg through being struck by a low bridge. In the case of Rouss vs. the New York Biscuit Company, before Judge Wallace in the United States circuit court, the jury recently returned a verdict for \$10,000 for the plaintiff. Rouss lost his right hand through an accident while at work in the defendant's factory. He sued to recover \$20,000.

Can Obligate Herself for Payment. That a married woman can render herself liable by special contract for the services of a physician in attending her, the Supreme Court of North Dakota says can not be doubted, under the statute of that State. And a married woman, who has in fact incurred liability for medical attendance made necessary by an injury for which an-

other is liable, the court holds, in the case of Chacey vs. City of Fargo, decided Nov. 4, 1895, may recover as part of her damages a sum equal to the amount of such liability the same as an unmarried woman, although she has not paid for such medical attendance at the time of trial.

Inebriate Retreats in Austria. According to *Hospital*, a plan of curative treatment of habitual drunkards is likely to be taken up by the government in Austria. It is proposed to establish retreats where inmates shall be received for two years. They may enter of their own accord, or be placed there under compulsion. The period of retention may be curtailed to one year, the patient being released on a system resembling that of ticket of leave. If a patient is shown to be incurable he may be committed for life.

Circumstantial Evidence of Abortion. In the case of Dixon vs. State, decided by the Supreme Court of Nebraska, Nov. 7, 1895, where there was evidence that the health of the girl upon whom it was charged that an abortion had been criminally produced had to the time of the use of an instrument therefor been good, and there was evidence tending to show that the fetus, when born, was well developed, the court holds that this was sufficient to justify the finding that it was alive, or vitalized; especially in view of the expert testimony which was introduced. There was affirmative evidence in this case that the woman in question had never been advised that such an act was necessary to preserve her life. There was also evidence that, down to the time of this event, she was a woman of, ordinarily good health. From these facts and from the other circumstances which the facts tended to prove, if the direct evidence was to be believed, the court holds that it was not only a fair inference, but it was an absolutely necessary inference, that the mother's life was not in danger, and that the object of performing the operation was not to save her life, but to prevent the birth of a child and to avoid disgrace. The inference was considered equally strong that no such operation had been advised by physicians as necessary to save her life.

The Twelfth International Medical Congress. The date of the Twelfth International Medical Congress, to be held in Moscow, has now been definitely fixed for the week August 19-26, 1897—cholera and the state of the political atmosphere permitting. The Czar has signed the Imperial Rescript sanctioning the congress, and His Majesty's uncle, the Grand Duke Sergi, Governor-General of Moscow, has consented to be its patron. The President will probably be Professor Klein, the Dean of the Medical Faculty of Moscow University; Professor Erismann, Professor of Hygiene in the same University, will be General Secretary. The Russian Government has granted a subvention of 120,000 francs toward the expenses of the congress. The official languages of the congress will be French and German.

British Medical Journal.

The Red Cross Advance in China. Dr. B. C. Atterbury, of Tientsin, China, is quoted by the *Christian Herald* as showing that the Red Cross is beginning to be appreciated by officers of high grade in that country. He is reported as saying:

"The Red Cross work, besides affording foreigners a fine opportunity to show practical sympathy with the suffering Chinese, has also stirred up some of the higher native officials to take an interest in their own soldiers. Many of the soldiers are most superstitious, and have great faith in the power of charms to heal their wounds. One general, with his arm shattered by a ball, thinking the daily dressing too slow a method of cure, called in a fortune teller. This charmer wrote some prayers on a piece of paper; this was burned and its ashes were made into a medicine, which was taken for four days. During this time the wound was not looked after, and the too superstitious general died from blood poisoning before the paper-prayer medicine had a chance to work properly. These men also believe most thoroughly in a certain plaster, which has not only power to draw out the bullet, but will also heal the wound without any after deformity. On the other hand, several more intelligent mandarins, seeing for themselves the su-

periority of the western surgery, have asked to have foreign trained men located in their camps, promising all necessary money for the hospitals. I have seen Viceroy Li several times since his return from Japan after signing the treaty of peace. The Viceroy is still the only official in China who appreciates and understands western civilization. The wound in his cheek has healed, leaving only a small dimple where the ball entered."

Liability of Corporations to pay Physician. *Deane vs. Gray Bros. Artificial Stone Paving Co.*, decided by the Supreme Court of California, Oct. 9, 1895, was an action brought by a physician and surgeon to recover the value of professional services alleged to have been rendered to one Barsotti for and under the employment of the defendant corporation. The trial court instructed the jury that it was an immaterial consideration whether Barsotti was or was not at the time of the accident to him in the employ of the defendant, if the defendant employed the plaintiff to treat him for his injuries. This was sound law, says the supreme court, if the principle of *ultra vires*, which forbids a corporation to exceed the powers conferred upon it, was not in the case, but certainly unsound if that question were properly presented. Except in the latter case, a moral obligation would support a contract of this character. The further instruction that if defendant knew that plaintiff was so treating him on its account, and relied upon the defendant, and defendant made no objection thereto, that defendant was liable in this action, the supreme court holds did not embrace a sound principle in law, and necessitated a reversal of the judgment, rendered for plaintiff in the court below. Whether it be claimed that such facts constituted a ratification or an estoppel, it is declared equally unsound. Certainly, the court says, the mere knowledge of a corporation that some one, perchance a total stranger, has represented that such corporation would compensate a third party for services rendered to such stranger, casts no duty upon the corporation to take any affirmative action. It is not for the corporation to disillusionize such party as to the reliance placed by him upon the statements, but rather his business to substantiate them before rendering the services. Therefore the court concludes that knowledge upon the part of the defendant that the plaintiff was rendering services to the injured man and was relying upon it for compensation for the performance of such services rendered, taken in connection with the fact that the defendant, possessing such knowledge, made no objection thereto, were circumstances wholly inadequate to create a legal liability against the defendant.

Concerning Ethics. Commenting upon the resignation of Dr. Cyrus Edson and the expulsion of Dr. Edward C. Mann from the Medical Society of the County of New York, the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, in its issue of Dec. 7, 1895, makes the following astonishing statement:

"It would appear that there has been sudden and unlooked for stimulation of the ethical conscience of a body that has for ten years or more been in affiliation with the 'no Code' State Medical Society. We trust that the change of heart is deep, sincere and not based on any alleged approaching bankruptcy of the New York profession. . . . The quickening of ethical conscience in the society, whereby professional honor is appealed to by many who have heretofore objected to any ethical rules, shows clearly enough the absolute necessity for rules of some sort. 'No Code' may be extremely interesting as a theory, but it invariably has commercialism as its underlying basis."

This proved a sufficient reason for the *Philadelphia Polyclinic*, in its issue of Dec. 14, 1895, to propound the following conundrums, which, in the vernacular of Dr. De Wolf Hopper Syntax, may be termed "corkers":

"We should like to ask the *JOURNAL* in all sincerity the following questions: *First*, is the signing of certificates of nostrums by a member of the New York County Medical Society, a no Code institution, more culpable than similar action on the part of a member of the *AMERICAN MEDICAL ASSOCIATION*? *Second*, is there any provision in the constitution or rules of the *AMERICAN MEDICAL ASSOCIATION* by which one of its officers who violates its Code of Ethics can be disciplined by the Association itself in the absence of action upon the part of his local society?"

We may with propriety add: *Third*, is it a greater moral crime against ethics to be a member of the Medical Society of the State of New York than to advertise in the various journals that one is prepared to go to any part of the country to do any sort of professional consulting or surgical work. We wait with some interest the JOURNAL's answer to these pertinent questions.—*Buffalo Medical Journal*.

ANSWER:—1. No.

2. Charges may be filed with the Judicial Council.

3. Degrees of "crime" are not anywhere stated in the Code.

Gray Hair Restored to Black.—Dr. George W. Griffiths of Louisville has contributed to the *Journal of Cutaneous and Genito-Urinary Diseases*, for September, a report of a case of which the following is an abstract:

"The subject of this report was an engineer, in the Fire Department of the city above named, 65 years of age, who was on duty during the alarming conflagration that occurred early in January of the past year. The night was bitterly cold, the streets being covered with snow and ice. He was out on duty from eleven o'clock in the night until two o'clock of the following afternoon, except when he was taken away overcome by sheer exhaustion, and sent in a carriage to his home, where he remained two or three hours and again returned to duty. Two or three sections of hose were leaking near his engine, and the spray was blown by a strong north wind until he was covered from head to foot with ice, which became so thick that it had to be cut or broken off from his clothing. This man was constantly at his engine, exposed to the north wind, which was carrying the spray of water from the broken hose. The top of his head was the warmest part of his body; his eyebrows and whiskers became wet, and were frozen stiff. He had a red skull-cap over his head, and his helmet on top of that: his head was not exposed at all, nor any hair, except the eyebrows and whiskers.

"I saw him the next day, when he had a very feeble pulse, and was much exhausted and worn out. He has not been in robust health for some time. The next afternoon after the exposure to the severe cold, as I have indicated, his hair turned black; and the wonder becomes greater when we consider that his hair was perfectly white before. He has been gray for eight years, and for the past three years perfectly white; before that he was blonde. Now his hair is black. I have known this gentleman for over forty years. The hair is oily, and does not seem to be dead at all. His head has been very carefully scrubbed several times, as I was inclined at first to think the change in color was caused by cinders or other foreign matter; but such did not prove to be the case."

Camping-out in Florida in Winter.—A Virginia correspondent of the *Independent* writes favorably of his experiences as to out-of-door life in the winter in Southern Florida.

"December and January are the coldest months, and these are best passed along the Gulf Coast, or on the east, south of Rockledge. The scenery is tropical and picturesque, and at this season the days are pleasant and the nights are cold enough to ensure sleep. Take your flannels and some knockabout clothing along, and, if you care for sport, add an assortment of fishing lines and your best shotgun. Do not take rifle or revolvers, unless you expect to make use of a wagon. Limit your toilet articles to absolute necessities. The shotgun and fishing tackle will be your best friends, and will render it easy for you to keep down expenses. The great point is to take just enough without touching on the superfluous. A favorite method with some campers is to hire a large covered wagon, similar to the almost obsolete 'prairie schooner,' and in this to make the tour of the State. They make camp anywhere along the roadside, or back on the bank of some lake or river, sleeping in their wagon and stopping wheresoever fancy suggests or night overtakes them. If there are three or four in the party, the expense is scarcely increased, the extra cost in one direction being saved in another. With a wagon many conveniences can be carried which should otherwise be avoided. If any of the party own rifles, these could be taken along, and would not be found amiss. In many parts of the State, there is large game. The permanent camp is the most comfortable and, if you are averse to exertion, perhaps the best; but wandering over the State is certainly the pleasantest and most in-

spiring. If this is your choice do not stop until you reach the extreme limit of your proposed area of travel—say, Punta Rassa or Charlotte Harbor on the west, or some of the coves or inlets of Indian River on the east. In this section the winter average of the mercury is about 70 to 75 degrees; and even very hot days, with light, off-shore winds, are generally followed by cool nights, in which that sultriness known to moist sections is seldom felt. One of the wonderful peculiarities of Florida is the rapid radiation and dispersion of heat after night-fall. I have slept night after night, for weeks and months, in a hammock slung between two pines, and even during the hot months of July and August rarely felt uncomfortable."

Medical Practice in Armenia.—An Armenian lady physician, now sojourning in Vienna, is reported in one of the London papers as having delivered a lecture showing the dark past and better prospects of the women of her land, in respect of medical care and a higher education. In the course of her lecture, she stated that she would have to deny Professor Albert's assertion as to the inferiority of women, as far as the Armenians are concerned. She said when the Armenian male looks around him, he can certainly not say that all he sees is man's handiwork, for it is rather woman's. The products of industry which have made the country famous—silks and wools, carpets and embroideries—are all made by women in Armenia, from the treatment of the raw material and the designs to the final process of manufacture. No male Armenian claims to have had a part in this work, nor does he dream of looking down upon woman as an inferior being. There is not a single proverb in all the dialects of the country that ridicules woman, although there are innumerable ones in her praise. Armenians say, "Let women learn all they can; they will be so much more useful, and we will marry them all the more willingly." She mentioned that women were now to be admitted to the St. Petersburg University, and predicted great results from this grand opportunity, as hundreds of families whose girls have passed through the grammar schools and seminaries in Tiflis, declared they should send them to study medicine, and so obtain relief from the terrible dearth of doctors in Armenia.

Hygienic Exposition of Warsaw. Consul Rawicz writes from Warsaw, Oct. 15, 1895:

The second Hygienic Exposition of Warsaw will be held in the city of Warsaw, Poland, during the year 1896. The exposition will be opened on the 15th of May, and will close on the 15th of July. The first hygienic exposition in Poland was in the year 1887, and, judging from the success which the undertaking met with at that time, and taking into consideration the interest shown at present among medical men and the public at large in hygiene, the usefulness of the new exposition would seem to be assured. At present there are nine committees at work: 1, physico-chemic; 2, parasital; 3, architectural; 4, pedagogic; 5, on hygiene of industry; 6, on hospitals; 7, pharmacutic; 8, statistic; and 9, public hygiene. The several committees have been assigned the following subjects:

1. The committee on physico-chemistry will take into consideration: *a*, air, water, light; *b*, food in general; and *c*, articles connected with the above, as kitchen utensils, paints, wall paper, and poisonous vegetables.

2. The parasital committee, the question of sterilization; also, the utensils used for the culture of bacilli, showing exhaustively the method of ascertaining their presence and the means for their destruction.

3. The architectural committee, human dwellings in general, past and present, and the latest improvements in hygienic building.

4. The pedagogic committee, the hygienic mode of caring for children; construction of school houses; all systems of school education, and school rooms and furniture.

5. The committee on hygiene of industry, the hygienic conditions prevailing in the homes of laborers, shops and factories; also, food and drink and vital statistics.

6. The committee on hospitals, the history and statistics of hygiene and the modern hospitals of the world.

7. The pharmacutic committee, the literature and history of pharmacy, patent medicines, furniture, medical instruments, and all pharmacutic results.

8. The committee on statistics, the blanks, plans, diagrams, drawings, books, and all printed matter on the subject of hygiene, meteorology, geology, hydrography and anthropology in all their details, and all sciences connected therewith; also, to provide a series of lectures and reports on its work.

9. The committee on public hygiene, the manner of living, dwellings, etc., of all classes of the population from a sanitary point of view.

Each of the above committees is composed of at least three members selected from among the doctors of medicine, professors, engineers and other specialists, under the presidency of the general committee, composed as follows: Professor Brodewski, President; Professor Przewski, Vice-President; Professor Proiecke, and Engineers Grotowski and Mascicki, members; and M. Polak, M.D., Secretary.

Awards of gold, silver, and bronze medals will be made; also, diplomas and letters of honor. *U. S. Consular Reports*, December, 1895.

A Lay View of German Chemists.—"Made in Germany" is now the recognized trade-mark for chemicals throughout the world. The dyes and by-products derived from coal tar have become a classical instance, or, as Bacon would have said, a glaring example. As we have stated, the fatherlanders have captured these trades from us. Go to Elberfeld, and what do we see? At the Farbenfabriken, besides first-class works, we are shown a laboratory unsurpassed, perhaps not equaled, in London, and employed in research or in the business there are sixty high-class chemists. In the Badische anilin und sodafabrik seventy-eight chemists are engaged. An expert witness told the Gresham commission that six skilled chemists was the maximum number employed in any English color works, if indeed, there were so many. These men are unceasingly active in research. The price to pay for progress is eternal vigilance. Every hint from England, France, America, or Italy is tried; every new material tested; every hopeful process patented. The great works at Höchst made in 1890 from 1,700 to 1,800 colors, they employed 3,000 hands, seventy chemists and twelve engineers. A firm in Offenbach with 300 workers had forty-five investigators. The lesson that has been driven home in the fatherland is that industrial processes carried on upon a large scale give great chances for discovery. Just as gas making gave anilin so the soap boilers' lye yielded iodine, the waste of salt gardens bromine, the mother liquors from the springs caesium and rubidium, the acid chambers selenium and thallium, the mines and metallurgical works gallium and germanium. Therefore, the "chemiker," on the other side of the Rhine, is always looking out for something new. He found it in the benzidin and azo dyes, the former giving Congo red and chrysamin, "the most important discovery of modern times so far as cotton dyeing is concerned." In short, as Dr. Ostwald has said, it is now a firm article of belief that "the secret of German industrial chemistry is the recognition that science is the best practice." In England it is greatly to be feared there still lingers faith in "the rule of thumb." *London Telegraph*.

The Visceral Complications of Erythema Exudativum Multiforme.

Osler (*American Journal of Medical Sciences*, December, 1895) describes eleven cases of erythema with especial reference to the visceral lesions. By exudative erythema he says that we understand a disease of unknown etiology with polymorphic skin lesions—hyperemia, edema, hemorrhage, arthritis occasionally and a variable number of visceral manifestations, of which the most important are gastro-intestinal crises, endocarditis, pericarditis, acute nephritis, and hemorrhage from the mucous surfaces. Recurrence is a special feature of the disease, and attacks may come on month after month, or even throughout a long period of years. Variability in the skin lesions is the rule, and a case may present in one attack the features of an angio-neurotic edema, in a second of a multi-forme or nodosum erythema, in a third those of peliosis rheumatica. The attacks may not be characterized by skin manifestations: the visceral symptoms alone may be present, and to the outward view the patient may have no indication whatever

of erythema exudativum. Of the eleven cases reported the visceral complications were as follows: In all gastro-intestinal crises—colic usually with vomiting and diarrhea; five had acute nephritis, which in two cases was followed by general anasarca and death; hematuria was present in three cases; hemorrhage from the bowels occurred in three cases, from the stomach in two cases, from the lungs in two cases, from the nose in three cases; one patient had spongy and bleeding gums; two patients presented enlargement of the spleen; in one there was recurring attacks of cough and bronchitis without fever; in one case there was a heart murmur. Five cases had swelling and pain in the joints. In only one of the cases reported was the attack single. In the others there were multiple outbreaks distributed over periods ranging from two months to eight years. The recurrence of severe attacks without cutaneous manifestations is a remarkable circumstance to which especial attention is directed. The relation of this disease to rheumatism and the question of the infective nature of the disease are not discussed because the author wished to emphasize the importance of the visceral manifestations of the process, which is also shown by the fact that in sixty-one cases collected by Osler (including the eleven cases now described for the first time) there were thirteen deaths, a percentage of 21.3.

The Etiology of Ozena.—Abel (*Zeitschrift für Hygiene und Infektionskrankheiten*, Bd. 21, Heft 1) concludes an elaborate bacteriologic and literary study of the processes included under the term ozena, as follows:

1. The mucous membrane of the nose is subject to a peculiar disease which begins with the appearance of isolated, minute masses of viscid muco-pus that rapidly dry into crusts. The process may extend and come to involve large districts of the nasal mucosa.
2. The above appearances are accompanied with actual changes in the mucous membrane; whether hypertrophy is the first change in all cases can not be said for certain, but the final result of the process is atrophy of the mucosa and hence the term rhinitis atrophicans.
3. In a series of these cases decomposition occurs in the crusts which is recognized by the unpleasant odor. This odor is an inconstant and secondary symptom. The cases in which it occurs are spoken of as examples of rhinitis atrophicans fetida or ozena (vera or simplex).
4. The disease may spread to the naso-pharynx—where it may also begin—to the accessory nasal cavities, the internal ear, the larynx and the trachea. The first noticeable change is the appearance of small masses of mucoid secretion.
5. The disease is an infectious one. The proof of this is seen in the transplantation of the process from the nose to the larynx or trachea of the same patient; the disease may also appear in several members of the same family. Finally the disease was produced experimentally in one case.
6. The cause of ozena is the bacillus mucosus ozenae, which is closely related to the pneumobacillus of Friedländer, but presents several important characteristics. This bacillus is found present in the mucus in every stage of the disease; it does not penetrate into the mucous membrane. Such bacilli are not found in the nose under other conditions. When the ozena heals the bacillus disappears.
7. In one case a pure culture was introduced into the healthy nose and the first stage of ozena was produced.
8. The atrophy of the mucous membrane that develops in the course of ozena may be explained as due to poisonous substances produced by the bacillus or as due in part, at any rate, to pressure of the crusts upon the mucous membrane, the epithelial lining of which undergoes metaplasia, changing from cylindrical to squamous.
9. The factor in many cases of rhinitis atrophicans is due to a fetid decomposition of the masses of secretion, but this de-

composition is not due to the bacillus mucosus but to the action of other microorganisms which invade the mucous secondarily. The variations in this secondary invasion will explain the absence of fetor in some of the cases.

The demonstration of the probable etiologic relation of the bacillus to the atrophierhinitis may at times become important from a diagnostic standpoint. The therapy which must be directed to destroying the bacillus necessarily meets with many difficulties on account of the numerous inaccessible cavities and recesses in the nose, and then the mucus in which the bacilli are imbedded protect the latter to some extent. The importance of careful prophylaxis in connection with the use of instruments and in order to prevent the spread of the disease from one member of the family to others is self-evident.

Practical Notes.

Iodoformin (Odorless Iodoform).—Eichengrün (*Therapeutische Monatshefte*, September, 1895) is convinced that hitherto no substitute has been found which can displace iodoform. They are mostly compounds holding iodine and giving it up by decomposition. But the action of iodoform is to be ascribed to a specific influence on the wound, rather than to the iodine. Still it is a matter of importance to remove the odor without changing the iodoform molecule or its power. The result of experiments is iodoformin, an odorless white powder, insoluble in the usual vehicles, which becomes iodoform on contact with acid or alkaline fluids. This change goes on *pari passu* with the healing process. Eichengrün further lays stress on the absence of irritation and a longer continuance of its activity than with iodoform. The yellow color remains longer in the wound.—*Deutsche Medicinische Wochenschrift*, Oct. 31, 1895.

Bromoform in Pertussis.—Trial was made by O. Fiertz (Inaug. Dis. Zürich, 1894) in seventy-five cases in private practice. The results were very favorable where the treatment was regularly carried out and continued fourteen days after cessation of the cough. In these cases the average duration of the paroxysms was 2.19 weeks, of the disease 3.19 weeks. In no case was the bromoform without effect. The rule for administration laid down by the writer is in brief: The initial dose in drops, for children up to ten years, should be the age plus two, given every six hours, preferably in a teaspoonful of sweetened water. Increase the dose one to two drops if the paroxysms do not abate within eight days. As soon as the paroxysms cease at night, give the dose once in eight hours. Use the remedy guardedly if the lungs threaten to fill with mucus. In case of intoxication from careless administration, use artificial respiration, wash out the stomach, give warm baths alternated with cold suffusions, moist swathing, fresh air.—*Deutsche Medicinische Wochenschrift*, Oct. 31, 1895.

Therapeutic Use of Bone Marrow.—Regarding the use of bone marrow dissolved in glycerin, it may be said that some American therapeutists have commended it far more emphatically than Dr. Pepper's words would appear to indicate. Dr. McLean Hamilton has used the glycerin of red marrow in nearly twenty cases with results that appear to cast older methods of treatment quite into the shade. One striking case may be summarized as follows: A female, aged 40 years, for several years has been hysterical, anemic and incapable of making exertion without resulting back- and headache. A year ago oöphorectomy was performed, but her nervous state and general mal-nutrition persisted. A variety of cerebro-spinal neurasthenic disturbances were helped little or not at all by treatment, and it seemed impossible to improve the condition of anemia. Corpuscular poverty well marked, the red corpuscles not exceeding 2,500,000 at any time. She was placed on medullary glycerid with prompt benefit. In doses of two drachms, thrice daily, she gained over 2,000,000 corpuscles in six weeks, and her hemoglobin rose to nearly fourteen grams. In cases in which anemic headaches were the prominent feature the effects of the marrow were marked, and many such improved in a few weeks. Two brominized epileptics were decidedly benefited, and this treatment must commend itself when iron

in such cases is apt to produce cerebral congestion and increase of the fits." The above remarks are quoted from a paper in the *New York Medical Journal*. Furthermore, Dr. I. N. Danforth, of Chicago, has treated a member of his own family with a similar preparation, and he believes that life was saved thereby. His preferred formula is the following:

R Liq. potass. arsenitis (Squibb's)	2.5	3	10
Acid phosphate (Hosford's)	3	oz.	90
Ext. bone marrow (Matthews')	to 8	oz.	240

Dose, one dessertspoonful after each meal.

Already a preparation of marrow, called carnogen, has been largely produced and put upon the New York market, purporting to be made from the medullary substance of small bones in combination with fibrin, and to have the qualities of stability and palatableness. It may be said in this connection that Dr. John S. Billings, Jr., made trial of a medullary extract at the Johns Hopkins Hospital in 1894, in four cases, two of pernicious anemia, and two of chlorosis. His results in the former disease were unsatisfactory, while he ascribes the benefits following its use in the other cases to the contained iron—a conclusion which, according to Dr. McLean Hamilton's analysis of the cases, does not seem to be borne out in those cases where red corpuscles are multiplied without any corresponding increase in the hemoglobin. To go a little further back in the history of this promising treatment for pernicious anemia, it may be said that Dr. Thomas R. Frazer, the well-known professor of materia medica and clinical medicine at the University of Edinburgh, is the parent of it, he having first reported upon it at the International Medical Congress at Rome. The first appearance of his paper in English dress was in the *British Medical Journal* for June 2, 1894, and in it the author makes no mention of the method of preparation of the remedy, but merely speaks of it as beef-bone marrow, leaving his readers to infer that the white marrow of the femurs of oxen was employed. Those who have followed him, however, have favored the use of the red marrow, obtainable from finely broken small bones, such as ribs, by extraction by glycerin. Dr. Hamilton gives the name "medullary glycerid" to the preparation used by him, and he advises those who have their uncured cases of anemia under mixed treatment, to give a fair trial to the marrow without other medicines.

Hospital Notes.

THE TRUSTEES of the Springfield, Mass., City Hospital held their annual meeting December 19. The expenditures were \$21,118 for the year, and receipts \$15,171, leaving a deficiency of \$5,946. The income of the hospital from rents and interest on invested funds was \$5,828. There were 355 patients treated in the year, including the 24 at the hospital last year. Of these 255 were discharged, having improved in health or recovered, and 44 died. A committee reported that it was expedient to build a large addition to the hospital, to cost \$12,000, and to contain one of the most complete operating rooms in New England. The room will be similar to the Sims operating room in connection with the Roosevelt Hospital in New York, which the committee visited. The building will be of brick, one story high and 46 feet long.

THE COMMISSIONERS to locate and build the new hospital for consumptives in Massachusetts have decided to locate it in the town of Rutland, Worcester County. Rutland is the highest town in the center of the State, and is 1,200 feet above the sea level. It is on the line of the Central Massachusetts Road and twelve miles from Worcester. The selection is a compromise between the eastern and western claims. No land has been bought, but prices have been obtained on about two hundred and twenty-five acres, at about \$8,000. The buildings will be begun next spring.

THE ELEVENTH annual report of the New York Post-Graduate Medical School and Hospital has been published. It embraces the period from Oct. 1, 1894, to Oct. 1, 1895. This hospital includes wards for babies, children and adults. In the last year 610 patients have been treated in the babies' wards and 1,125 in the children's and adults'. Its dispensary, which is for the poor only, has treated 19,227 persons, and 866 visits have been made by the district physician to the patients' homes.

Washington Notes.

HEALTH OFFICE WEEKLY REPORT.—The report of the Health officer for the week ended December 21, is as follows: Number of deaths (still-births not included) 103. Death rate per 1,000 per annum, 19.4; death rate per 1,000 per annum corresponding week last year, 15.7. The number of deaths reported at the Health Department fell off during the last week. From 110 the mortality declined to 103, and the annual death rate went down from 20.8 to 19.4. The improvement was general. Nearly one-third of all the deaths were from lung diseases, of which 15 were from consumption and 13 from pneumonia. With the exception of two deaths from diphtheria and one from scarlet fever the dangerous contagious diseases were in abeyance. There were eight deaths from typhoid fever and one from malarial fever. Of all who died forty were over 50 years of age while twenty-two were under 5 years old. With the death rate materially below the normal and with no immediately threatening epidemic the health conditions may be pronounced favorable.

HOSPITAL APPOINTMENT. Dr. Francis R. Hagner, late resident physician at the Children's Hospital in this city, has been appointed on the house staff at the Johns Hopkins Hospital at Baltimore, Md. The Doctor is the son of Dr. Chas. E. Hagner of this city and a graduate of the Columbian Medical School.

A NEW FREE DISPENSARY.—The Central Union Mission has organized a free dispensary in the old postoffice building.

THE GROSS PEDESTAL.—The contract for the erection of the pedestal for the Gross statue has been awarded to a local firm. The price to be paid is \$1,400. The pedestal is to be of round block granite. Work will begin at once.

Detroit Notes.

The regular meeting of the Wayne County Medical Society was held Thursday, December 26, at the Hotel Cadillac, where about one hundred physicians of that city sat down to a course supper at 8:30 p.m. After the repeat Dr. Mathew D. Mann, of Buffalo, N. Y., read a paper on "Some Common Mistakes in Gynecology." The Doctor took issue with the older writers upon the subject of cancer where they state that pain is a prominent symptom of the disease, and stated that the opposite was what he had found to be the rule, that a cancerous condition of any of the organs in the female pelvis showed that those afflicted were at the first almost entirely free from pain. The Doctor cited several cases, among them one that was brought to him by a brother practitioner, in which he was obliged to take some pains to show the family physician that his patient was suffering from a malignant trouble. The Doctor laid great stress upon making a thorough examination of the pelvic organs, as only by an early diagnosis could the physician hope to accomplish much for the patient. As a rule the early diagnosis was not made and the surgeon was unable to give the desired relief. The aorta and the spinal column he had seen mistaken for tumors; and the patients themselves sometimes will insist that they have tumors. One case was cited in which there was such marked pain that he was obliged to make an exploratory incision to satisfy the patient. This relieved the patient from the pain, but he would not advise this procedure, except in extreme cases. He had patients brought to him by the attending physician for supposed tumor in front of the rectum, which turned out to be the uterus; and had known patients to examine themselves in this way, and arrive at the conclusion that they had something that must be removed. The Doctor dwelt upon this mode of examination as one in which the uterus could be well examined, also the ligaments and the ovaries. The Doctor next asked his hearers to remember the ureter and not remove ovaries when the fault lies with the former. The Doctor here laughed at the idea that the uterus, an organ weighing some three ounces, lying upon the bladder would bring about cystitis, as he showed we have tumors weighing more than

that many pounds, lying against and pressing down upon the bladder, without giving any symptoms of inflammation of that organ; but more often there was some trouble in the walls of the bladder itself, or in the secreting fluid; that when the urates or crystals were removed, the urine neutralized, the trouble would cease, and recommended for treatment in this class of cases, the taking of large quantities of pure alkaline water, lithia or others. Personally he found that the water did not contain enough bicarbonate of soda, and so he added some alkalin and gave liberally large draughts. He gave the history of a patient at his private hospital, where the patient, according to her own statement, had not taken a glass of water altogether for months, and he was obliged to start with teaspoonful doses. In constipation he recommends cascara, with washing out with a long rectal tube of bowel and massage to the abdomen. Where patients were weak he recommended massage with some bland applications of lanolin, etc., and considerable outdoor exercise. As to pessaries, he would certainly very much regret to do without them, especially in retroflexion, as he thought that he had accomplished a great deal in the distressing train of symptoms that this trouble brought on. There were cases outside of the operative field where only the pessary could give relief. The following gentlemen made remarks on the paper: Drs. E. W. Jenks, H. O. Walker, N. W. Longyear, Walter P. Manton, Donald Maclean, L. E. Maire, of Detroit; Charles B. Nancrede, of Ann Arbor, and G. R. Cruikshank and James Samson, of Windsor, Ontario.

THE DETROIT MEDICAL AND LIBRARY ASSOCIATION at its regular meeting, Monday, December 16, listened to an interesting paper by Dr. J. E. Emerson, entitled "The Consideration of Certain Heart Tonics." At the next regular meeting of this society, Monday, December 30, Dr. Geo. Henry Fox will read a paper entitled "Lesions of Various Cutaneous Diseases."

HEALTH OFFICE REPORT for week ending Dec. 28, 1895: Deaths under 5 years, 39; total 78. Births, male 41, female 46, total 87. Contagious diseases: Diphtheria, last report 33, new cases 23, recovered 20, died 2, now sick 34. Scarlet fever, last report 21, new cases 6, recovered 5, died 0, now sick 22. Smallpox, last report 3, new cases 0, recovered 0, died 1, now sick 2.

Change of Address.

Ingals, E. Fletcher, residence to 4757 Grand Boulevard, Chicago.
McKinlock, J., from Lakota Hotel to 3622 Michigan Avenue, Chicago, Ill.
Perry, T. B., from Milledgeville, Ga., to U. S. Marine Hospital Service, Buffalo, N. Y.
White, P., from Rockford to Van Orin, Ill.

ADDRESS.

A SHORT SKETCH OF THE HISTORY OF GYNECOLOGIC SURGERY.

Opening Address before the Medical Department of the Minnesota State
University, October 8, 1895.

BY ARCHIBALD MACLAREN, A.M., M.D.

ST. PAUL, MINN.

In the busy rush of professional work and daily practice, it will, perhaps, prove of benefit to take a glance backward and for a few moments study the early beginnings of our most glorious profession—glorious for what it has achieved, more glorious still for the charity which its individual members are daily distributing to the pauper sick throughout the world.

In most of the recent text-books of to-day one would imagine that surgery was almost entirely due to the invention and ingenuity of the various text-book authors, and that little or nothing is due to our illustrious predecessors in medicine. Many hundreds of years before Christ, medicine had made considerable progress, as shown by the inscriptions on the Egyptian monuments, as well as by the five medical papyri of very ancient date. On the walls of the Egyptian temples are found figure pictures representing the surgeon operating upon his patient; fillings of gold and false teeth found in Egyptian mummies show that dental surgery had made very considerable advance, even at this early day. Susruta, a Sanskrit work of uncertain date, written at least 500 years B. C., proves that the specialists were commencing to be recognized as important agents in the commonwealth even at this early date. Nail trimmers, ear borers, tooth drawers, and drawers of blood and lithotomists are mentioned among others. But medicine was at this time so closely allied to mysticism and confounded with the supernatural, that little scientific knowledge was realized until the time of Hippocrates, called the "great," born about 470 B. C. This man, who is justly called the "Father of Medicine," was supposed to be the direct lineal descendant of Æsculapius, a priest physician who founded an order of priest physicians called Asclepiadæ. These priests established several temples of health throughout Greece and Rome, built especially in the high places where the "air was wholesome," or at the medicinal springs. At these temples patients were received and treated somewhat after the manner of our modern hospitals.

In the beginning of the fifth century, B. C., there were three of these temples of special importance, namely: the temples of Rhodes, Cnidos and Cos. The last named is of particular interest to us, because it was here that the young Hippocrates received his education and grew to the renown which gave him the name of the "Great Hippocrates." He succeeded his father, becoming high-priest physician, in charge

of the temple, and the head of the school of physicians, called the School of Cos. The course of treatment at these hospitals included baths, rubbings, shampoos or massage, restrictions of diet, the administration of drugs and occasional surgical operations, combined with religious ceremonials and music. It has even been suggested that animal magnetism and hypnotism were made to serve their part in effecting the cure of the patient. The extensive physical notes or histories of the patient, which were kept by the priest students, or hospital internes, show the desire for exact knowledge which these men were striving after. That Hippocrates studied these histories carefully is shown by his renown in all the civilized world for his great powers of accurate prognosis. His fame was so great that he was called at one time to Athens to stay the plague; again to Babylon to treat the king of Persia, where he remained in attendance upon this royal personage, as resident physician, for several years.

To show the character and breadth of mind of Hippocrates, how free from errors of superstition he was, if you will pardon me, I will quote a few sentences from Francis Adams' translation of the original Greek manuscripts, where, in speaking of the "sacred disease," or epilepsy, he says:

"It is thus with regard to the disease called Sacred; it appears to me to be nowise more divine nor more sacred than other diseases, but has a natural cause from which it originates like other affections. Men regard its nature and cause as divine from ignorance and wonder, because it is not at all like to other diseases. But if it is reckoned divine because it is wonderful, instead of one there are many diseases which would be sacred. And they who first referred this disease to the gods, appear to me to have been just such persons as the conjurors, purificators, mountebanks and charletans now are, who give themselves out as being excessively religious, and knowing more than other people. Such persons, then, using the divinity as the pretext and screen of their own ignorance."

In regard to the knowledge of this man in both medical and surgical matters, I can but express to you the pleasure and surprise which I have experienced from reading his remarkable works. His knowledge of the effects of the physical surroundings of the patient, the effects of heredity and previous disease is quite remarkable. Pulmonary tuberculosis, as well as tubercular inflammations in other parts of the body, was recognized by Hippocrates. In surgical matters his works show a very considerable knowledge; especially is this true in reference to injuries of the bones, fractures and dislocations, to each of which subjects he devotes a book.

The accidents of the amphitheater and the Olympian games probably furnished him with plenty of clinic material. Hippocrates speaks frequently of the use

of the elevators and the trephines in injuries of the head, and if I understand him aright, he also at times uses the trephine in epilepsy. Hippocrates advises and practices tapping of both the abdominal and the chest cavities for the purpose of withdrawing collections of fluid. Hernia in some of its forms was well understood by Hippocrates and his pupils. The treatment of the falling of the intestine into the scrotum by position, enemata and taxis, is described; he also speaks of the production of the omental hernia from straining of epileptic convulsions. That he was familiar with the symptoms of stone, both in the kidney and the bladder, is shown in several places in his writings. He describes the symptoms of renal calculus and the use of the sound in detecting stone in the bladder.

In the "oath" of Hippocrates, with reference to this very matter, he says: "I will not cut persons laboring under the stone, but will leave this to be done by men who are practitioners of this work." The operation of lithotomy was at this time and for many hundreds of years after, not considered respectable, and was left with the same class of men who performed castration for the purpose of making royal eunuchs.

This "oath" of Hippocrates, to which it was common for physicians of later years to give their assent, is of interest in regard to the standing of morality and propriety, which it enjoins. It was more than anything else, however, a compact between the physician and his student, whom he promises to treat as a son and to instruct in all of the science of healing.

With regard to the diseases of women, displacement of the uterus and its treatment by pessaries, is understood to a limited extent. Medicinal pessaries for the treatment of uterine troubles, intra-uterine pessaries for the production of abortion are spoken of, but only to condemn. Ulcer of the cervix which is, as he says, "produced by parturition," and later, "when an ulcer heals, the neck of the womb is harder, smoother, and the woman is less liable to conceive." It is remarkable to me how near Hippocrates comes to the appreciation of laceration of the cervix in this description of his, for although ulcer of the womb was described and treated until the present generation, it was reserved to our own Thomas Addis Emmett to prove that such lacerations were, in fact, tears, and that certain of them could only be cured by trachelorrhaphy, the operation which was devised and practiced by Emmett in New York during the past thirty-three years.

Pyometria, or collections of pus in the uterus, is described by Hippocrates, and also dropsy of the uterus, which may have been the condition which we recognize as ovarian cyst. Hydatids of the uterus he also describes, which he believes to be caused by drinking marsh waters. Abscess of the uterus, which starts near the hip-joint and bursts at the side of the uterus, is, without doubt, our pelvic abscess, rising from suppuration of the ovaries or fallopian tubes, instead of the uterus, as he describes. He advises the treatment of this condition with tents for the promotion of drainage through the vaginal opening, much in the same way as drainage is secured to-day.

Rectal diseases were apparently very well understood, and the use of the rectal speculum; although the use of the speculum in the vagina is not mentioned, it undoubtedly must have been used, for without it his accurate description of the ulcers of the womb would have been impossible.

External and internal hemorrhoids, the treatment of hemorrhoids, either by strangulation with the ligature, or by searing with a hot iron, the hot iron being passed into the rectum through a canula, corresponds, as you see, very closely with the usual line of treatment of hemorrhoids to-day. Fistula in ano is accurately described, with the advice that the abscess be opened before it bursts into the bowel, if possible, but after the fistula has formed, he advises the dividing of it by the tightening of a ligature or occasionally with a knife.

Following Hippocrates the next surgeon of importance in history is Galen. He lived and practiced 150 years after Christ. He has given to us several very extensive works on the subject of medicine and surgery in Greek, the study of which will well repay the student of surgery to-day. That surgery had made considerable further advance at this time is shown in his accurate description of laparotomy for intestinal concretion—probably the condition which we recognize as intestinal obstruction. The incision he makes a little to the left of the median line just below the umbilicus. After exposing and opening the intestine and relieving the obstruction he completed his operation by an intestinal suture, probably of linen thread and a closure of the abdominal wound. Galen also gives a very accurate description of the operation which is so well known by the name of Cæsarean section. I have not been able to determine that the name is justified in the birth of Cæsar by this method, but it is not impossible that this was the case, for I find records of several well-known men of a somewhat later date who were saved by Cæsarean section upon dead women; as for instance, the philosopher Georgia, who was so delivered according to Valerius Maximus, and Pliny says that Scipio Africanus was also saved from death by this same operation. I understand that Galen does not advise the operation upon live women, but in ancient times and even to-day in the Catholic countries, Numa's law provides for the opening of the abdomen in all dead women who are large with child. Velpeau quotes M. C. Lang to prove that Nicholas De Falcon was the first surgeon to perform this operation upon a live woman. This was in the year 1491. The operation was greatly lauded and very much abused by the different authors of 200 years ago—certain men like Mauriceau, who wrote in the year 1700, condemning it as entirely unjustifiable and doubting the list of successful cases which were reported by his predecessors. Certainly the operation was much abused, for, as Velpeau says, it was as popular in France as blood-letting was in England. The operation soon fell into disuse on account of the great maternal mortality, only to be revived with great success under the present antiseptic regime.

With regard to the use of the forceps in childbirth, it is supposed that the ancients used some such contrivance in difficult labors. None of the older authorities give record of it, but in the ruins of Pompeii, in what is supposed to have been a physician's office, together with a rectal speculum, were found a pair of forceps which could only have been meant for obstetric work. In later years the forceps were invented by a young man named Chamberlens about the year 1655. The Chamberlens brothers kept the knowledge of the existence of the forceps and of their use a secret for quite a number of years. That this secret was profitable to them is proved by authorities who

claim that the older Chamberlens' practice gave him thirty thousand pounds a year, a very large sum for that early date. Chamberlens took his forceps with him to Paris for the purpose of selling them to the French government, but making the mistake that he could deliver any woman, no matter what the obstruction, with the forceps, he attempted to deliver a rachitic dwarf whom Mauriceau had said could only be delivered by Cæsarean section. Chamberlens of course failed, as well as his negotiations with the French government.

While speaking of obstetrics it may be of interest to know Mauriceau's opinion of the fertility of the women of the time. He says that although four children at a birth is generally conceded to be the limit, he reports many instances in which more were born at one birth and until the number reaches fifteen he seems to think that such records are just within the bounds of possibility, but when he arrives at the history of a certain Dame Marguerite, Countess of Holland, "who in the year 1276 was brought to bed with 365 infants at one and the same time, who all received baptism and died on the same day together with their mother," he confesses, and not without reason, that we have reached the domain of fable.

Vaginal hysterectomy. According to Velpeau, "Soranus, a Roman obstetrician living in the reign of the Emperor Hadrian, affirms that the uterus may be removed without causing death, as Themison," he says, "demonstrates in his writings"; and he even goes so far as to lay down the operation as a precept, for he recognizes without any reserve, that the prolapsed uterus should be extirpated if it is in a putrefied state and asserts that it has been in some cases excised entire with success. Several operators, among others Brengarius of Bologna, in 1507, describes the removal of the inverted uterus with a ligature. For malignant disease Patella was probably the first operator to remove the uterus. The operation was performed on April 13, 1812. According to Senn, Patella did not know that he had extirpated the entire uterus until he had examined the specimen after the completion of the operation. The patient died at the end of the third day. Senn says that J. C. M. Langenbeck, the grandfather of the Langenbeck of our time, living in Göttingen, made the first deliberate attempt for removal of the uterus through the vagina for cancer in the year 1813. Senn gives a long and very interesting description of this first operation, which was done, as all operations were at that time, without the aid of any anæsthetic. In this operation the surgeon dissected the uterus out of its peritoneal coat without opening the abdominal cavity. His colleague, who was very gouty, toward the latter part of the operation gave up entirely and could be of no assistance. Langenbeck found it necessary to tie the ligatures holding one end in his teeth, and to stop the tremendous hemorrhage which followed the removal of the uterus by thrusting his closed fist into the cavity from which the organ had been removed. The patient apparently died upon the table, but later revived, and lived without return of the growth for twenty-six years. Langenbeck's assistant soon dying of the gout there was no one to corroborate his story and his report of the operation was never believed until the autopsy was performed twenty-six years after the original operation. The second operation for deliberate vaginal hysterectomy was performed in the year 1882 by Sauter. Billroth, Velpeau and

others have given the credit to Sauter of first performing this operation, when it should rightfully belong to Langenbeck.

After the invasion of Rome by the barbarians from the north of Europe and the consequent downfall of the Roman empire, all scientific knowledge received a set-back from which it did not recover until the great renaissance in the fifteenth century. Medicine and surgery suffered with the other sciences, the Arabs and the Catholic clergy being the only ones to keep alive the ancient knowledge. The diseases of women suffered more than general medicine and surgery, because of the seclusion of the women by the Mohammedans and on account of the celibacy of the priests.

France was the first to revive the study of the diseases of women, and under such men as Ambroise Paré, who revived the use of the speculum forgotten since the days of Soranus; Recamier, who has given us the uterine sound and the curette; Jobert de Lambelle, who successfully operated upon vesico-vaginal fistulæ; Madame Boivin and many others, has helped to bring gynecology up to its present standing.

As Americans we can justly be very proud of our part in furthering all gynecologic and abdominal surgery. Ovariectomy, although it had been suggested and advised by John Bell, instructor in anatomy and surgery in the University of Edinburgh, was never performed by him nor by any of his students excepting the courageous Ephraim McDowell, of Danville, Ky. Young McDowell had graduated from the University of Edinburgh, had listened to the lectures of his preceptor and afterward lived with him as a student and assistant. Several years after McDowell had entered upon the practice of his profession in Kentucky he met with his first case of ovarian cyst. He suggested to his patient, Mrs. Crawford, the only chance of escape from her disease, and she accepted it without hesitation. This, the first operation of the kind ever performed, was done while a mob of enraged neighbors awaited upon the outside of the house the result of the operation, determined to lynch McDowell if his patient did not recover. Fortunately for him and for her the operation was crowned with success and she lived for many years. In 1818 McDowell prepared a brief report of his first three cases and sent it to the *Eclectic Repertory and Analytical Review*, published in October, 1816, in Philadelphia.

Mr. Lizars, associated with Mr. Bell in Glasgow, received a report of these cases sent him by McDowell and a few years later operated for the removal of an ovarian tumor in Edinburgh. Tait and others have tried to claim that Lizars was the first ovariectomist, but history will not bear them out. One or two operations had been performed before the time of McDowell's, but they were simply the tapping or opening of ovarian cysts with a knife, no attempt being made to remove the sack or to ligate the pedicle. Probably no other one operation since surgery became an art has done so much to save life and to alleviate suffering as has ovariectomy, and certainly all honor should be due to the father of ovariectomy who has had the courage to perform this operation.

Nothing that has ever happened has done more to develop surgery than the discovery of anesthesia. On October 16, 1846, Dr. Morton, a dentist living near Boston, having experimented upon himself and a few of his friends, etherized a patient at the Massachusetts General Hospital, making it possible to per-

form considerable of an operation without giving the patient any pain. That the dread of surgery to-day is bad enough we all must admit, but what could it have been before the days of ether and chloroform? It is certainly wonderful that so much was accomplished and that patients, and especially women, could be brought to the point of undergoing such terrible suffering as must have been inflicted by even the slightest surgical operation before the days of anesthetics. Gynecologic, and especially plastic surgery of the vagina, made very rapid progress after the introduction of ether. The two men in this country who have done the most to develop a high standing of American gynecology are Marion Sims and Thomas Addis Emmett, both of New York. Sims, when he was a country practitioner in Georgia, in an emergency needing a speculum, improvised one from a piece of malleable metal, from which grew the Sims speculum of to-day, upon which all of the perineal retracting specula are modeled. The use of the Sims speculum and Sims position allowed a thorough inspection of the vagina and made the cure of vesicovaginal fistula a certainty, where before it had been the exception when such conditions were cured. Emmett, by his introduction of silver wire as a suture material, also greatly aided vaginal plastic surgery.

In the Johns Hopkins Hospital in the last few months investigations have been carried out to prove that silver has an inhibitory action upon growing bacteria. Perhaps this was one of the reasons why Emmett, with his silver wire, was able to secure such excellent results in distinction to any other suture material then in use. Emmett discovered the condition known as laceration of the cervix, and invented the operation for its cure which bears his name. His perineal operation is founded upon sound surgical principles, and so far as my observation has led me, every surgeon who has ever mastered this intricate procedure believes, with its author, that it is the only perineal operation.

Abdominal hysterectomy, which a few years ago was one of the most dangerous of all abdominal operations, has become to-day no more dangerous than ovariectomy was five years ago. This has been accomplished by the observation of another American, Baer, of Philadelphia. The old operation, in which the cervix was constructed in mass and fastened in the lower angle of the abdominal wound, where it was left to slough off, has been superseded by the intra-peritoneal treatment of the stump which consists of the ligation of the four arteries which supply the uterus with blood and the suture of a flap of the periotomy over the stump of the cervix, which is not constricted in any way.

One of the most brilliant recent advances in surgery must be credited to Howard A. Kelly, of Johns Hopkins. By the use of his ureteral specula and the placing of the patient in the knee-chest position, he has made it possible to see the entire mucous lining of the bladder and to catheterize the ureters upon sight, and even pass his long elastic catheters into the pelvis of the kidney itself, making possible accuracy in diagnosis and treatment which would not have been thought possible a few months ago.

You are entering or have entered upon the study of the most interesting of all human problems, the study of the secrets of life itself; that you may all attain your highest ambitions in your chosen profession is the sincere desire of myself and of all your instructors.

ORIGINAL ARTICLES.

THIERSCH'S METHOD OF SKIN GRAFTING.

Read in the Section on Surgery and Anatomy at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY J. C. OLIVER, M.D.

SURGEON TO THE CINCINNATI HOSPITAL; SURGEON TO CHRIST'S HOSPITAL;
SURGEON TO THE PRESBYTERIAN HOSPITAL; PROFESSOR OF DESCRIPTIVE ANATOMY AT MIAMI MEDICAL COLLEGE.
CINCINNATI, OHIO.

Although a comparatively new procedure in surgery Thiersch's method of skin grafting has met with considerable favor among surgeons. Now that a sufficient time has elapsed to test the permanency of the earlier results, this method should be accorded a more prominent place in plastic surgery. Its field of application is limited to three conditions; 1, where one desires to prevent deformities produced by healing by granulation; 2, when large areas uncovered by skin are to be healed promptly; 3, where one desires to replace cicatricial tissue by skin grafts in order to restore the usefulness of the parts. The raw surfaces left by burns of the skin are, as is well known, slow to heal when left to the natural methods, and the contraction of the cicatricial tissue produced by the healing, frequently seriously disturbs the function of the part. This offers a very good field for the application of Thiersch grafts.

It very frequently happens after the removal of extensive tumors that it is impossible to draw the edges of the flaps of the skin together and thus a raw surface is left to heal by granulation. Such surfaces as these may very conveniently and with a great degree of certainty and satisfaction be rapidly healed by covering them with skin grafts at the time of the original operation or later.

Ulcers of all descriptions except syphilitic, uncovered areas left by sloughing of flaps and similar conditions afford a good field for this method.

Instances when skin grafts can with advantage be substituted for cicatricial tissue, are by no means uncommon. Discolorations of the skin such as "port wine stains," may be cut out and skin with a normal color be substituted therefor.

Much of the horrible deformity resulting from the removal of malignant growths about the face can be avoided by the use of Thiersch grafts.

The technique of the method is comparatively simple. An absolute essential is the careful preparation of the patient for the operation. The area to be grafted and the region from which grafts are to be secured (usually the skin of the thigh), must be thoroughly sterilized previous to the day of operation. When the grafting is to be done on old surfaces which have been bathed in pus for a greater or less time, it seems advisable to begin the sterilization of the ulcer several days before the time of grafting. For this purpose dressings saturated with carbolic or bichlorid lotion should be kept constantly in contact with the part. After the parts have been properly prepared for operation a sharp spoon is used for the purpose of scraping away the granulations which cover the ulcer. This layer of granulations is often surprisingly thick, but the sharp spoon should scrape all away until the firm base of the ulcer is reached. The edges of the ulcer, which are usually thick and indurated, should also be thoroughly curetted and a raw, bleeding surface left. After this has been done the oozing from the surface may be very satisfactorily

stopped by elevation of the limb and pressure from hot sponges. The Esmarch tourniquet has been recommended to control the oozing from the scraped surface, but experience has seemed to demonstrate the fact that the oozing which occurs after the tourniquet is removed and takes place under the grafts, thus lifting them off their bed of tissue, does harm, especially when dealing with an old suppurating surface. The blood-clot then seems to form an excellent culture medium for the pyogenic organisms and suppuration occurs early after the grafting, thus seriously endangering the success of the operation. In those cases in which an aseptic field is to be grafted, the objection to the use of the tourniquet would not be so serious a one. Nevertheless, its use is unnecessary for the reason that pressure and elevation of the parts is sufficient to bring about an early cessation of oozing.

After obtaining a dry surface upon which to implant the grafts, the next step is to cut the ribbons of skin. This is best done by means of a very sharp razor which has been ground flat on its under surface. The hands of your assistant are used on each side of the thigh in such a manner as to render the skin tense; then, with a sawing motion backward and forward of the razor, the upper layers of the skin are removed for a distance of an inch or two. The incision of the skin does not pass into the deeper layers; all that is necessary is to enter the papillary layer of the integument. As the graft is cut by the razor it will ordinarily fold up upon that instrument, and may be conveniently transferred upon it. The layer of skin is now spread out upon the surface to be grafted. This can be much facilitated by the use of a couple of probes, wet either in sterilized water or with the physiologic salt solution. Care should be taken to spread the graft out evenly upon the raw surface. In like manner other grafts are cut and applied. The edges of the grafts should overlap each other and also the margin of the surface. When covered completely with these strips of skin, the dressing should be applied so as to retain them in position. Various methods of dressing such surfaces have been recommended. Thiersch himself recommended that they be covered with rubber tissue. Later work in this line seems to demonstrate the fact that the nature of the dressings is not so important as was at first supposed. Most operators, following the lead of Thiersch, still adhere to wet dressings for several days at least after the grafting has been done. Other observers have reported excellent results from the use of dry dressings. It seems probable, therefore, that wet or dry dressings may be used at the option of the operator. It may even be predicted that here, as elsewhere in surgery, dry dressings will supersede wet.

One word as to the treatment of the areas from which the grafts are taken. Patients frequently complain most bitterly of pain and annoyance produced by these raw surfaces. The ordinary dressings are not well adapted for this purpose because of the irritation produced by the adhesion of the gauze to the raw, sensitive surface. The redressing is unpleasant and painful and likely to cause suppuration. The use of gauze saturated with sterilized oil, containing 1 per cent. of carbolic acid, has been found to be much more satisfactory both to the physician and the patient. Healing goes on rapidly and is painless. Ordinarily there will be no necessity for changing such a dressing until the surface is healed.

Various suggestions have been made for the purpose of simplifying the technique of this operation. S. J. Mixer in the *Boston Medical and Surgical Journal*, vol. cxxv, page 700, suggests the use of a roller and special knife for the purpose of cutting the grafts more accurately and easily. His suggestion in regard to raising the grafts from their bed by means of properly sterilized tissue paper is undoubtedly a good one, and saves the curling up of sections after they have been cut. The same method is used in dealing with large thin sections for microscopic use, cut with the microtome.

The thorough sterilization and preparation of the area to be grafted is of prime importance and should therefore receive very careful attention. Most writers condemn the use of a strong antiseptic after the surface has been curetted for fear its use may damage the capillary circulation. Some writers, however, advise its use after the surface has been curetted, as they believe its application may prevent suppuration. The plan has been adopted successfully. It would seem better, however, to wash away the excess of antiseptic with plain sterilized water before applying the grafts to the surface.

Dr. F. W. Murray in the *New York Medical Journal* of Feb. 4, 1893, calls attention to the peculiar keloid-like development which occasionally takes place between and beneath Thiersch grafts. It would be interesting to know whether this complication occurs more frequently in the negro race as does ordinary keloid. The author says nothing upon this point.

It is probable, from microscopic investigations which have been made, that the blood supply of the grafts is very speedily established and a firm union occurs within a very short time providing suppuration does not take place early. Suppuration later, after several days, does not appear to exert a very detrimental effect upon the grafts.

Occasionally at the time of the first dressing it seems as if all the grafts had died, but after a few days more it is seen that the grafts are still alive and are growing. Excellent results are sometimes obtained when it looks as if all the grafts had been destroyed.

In making skin grafts no fear need be felt about transplanting skin from a region in which hair is normally present to one in which it is normally absent. The hair does not grow in the grafts, because the hair bulbs are not included in the portion of skin removed.

Within a few weeks my colleague, Dr. Evans, placed skin grafts upon the bony surface of the skull after having cut away the external table sufficiently to provoke slight bleeding. These grafts took excellently and thereby an old exposed area of the skull was covered.

Syphilis seems to have a very blighting influence upon the vitality of skin grafts, and because of this fact skin grafting can not with confidence be recommended in the ulcerations produced by that disease. The possibility of inoculating persons with syphilis should be borne in mind when the grafts are taken from one person and engrafted upon another. Instances are on record where syphilis has been produced in this way. Other diseases might also be communicated in this way, and therefore it is wise, whenever possible, to take the grafts from some part of the patient's own body.

By way of illustrating the good results obtained by this method of skin grafting, I desire to report two cases representing two different conditions for which grafting was done. The first case illustrates the advantage to be gained by substituting skin grafts for cicatricial tissue. The second illustrates the applicability of this method to the covering of large defects caused by sloughing of flaps. It also incidentally illustrates the fact pointed out by Francis S. Watson in the *Boston Medical and Surgical Journal*, Oct. 27, 1892, that it is unnecessary to curette the surface to be grafted providing it be covered by healthy, fresh, red granulation tissue.

Case 1. Miss Grace L., age 18, had her right hand caught between hot rollers while at work in a laundry. The palmar surface was very severely burned and was allowed to heal by granulation. She came under my observation about one year subsequent to her accident. The contraction resulting from the healing had drawn the little finger down to about a right angle, and the thumb inward across the palm of the hand in such a way as to prevent its being brought into contact with the ends of the fingers. The index, middle and ring fingers possessed good motion, the superficial flexors being free from involvement. The palm of the hand was a mass of cicatricial tissue of low vitality. Superficial ulcerated points were present in two or three places.

As the patient was one dependent upon herself for her means of livelihood, and the use of her right hand was a matter of great importance, she was advised to have the scar tissue removed and its place supplied by skin grafts. This was agreed to, and on Nov. 17, 1894, the scar tissue was thoroughly dissected out in the palm of the hand and Thiersch grafts from the thigh were substituted. Dry dressings were used and the grafts took perfectly. After healing was completed the thumb could be approximated to the end of each finger and motion was excellent except in the little finger, where some scar tissue about the second interphalangeal joint was allowed to remain. The patient now makes her living by wrapping cakes of chewing gum. The nature of her occupation indicates that the use of her hand must be nearly perfect.

Case 2. On Jan. 1, 1892, I made a double amputation of the legs of a man who had had these members crushed by a switch engine. As it was impossible to tell just how far the vitality of the skin was destroyed, the amputation was made a couple of inches above the apparent line of destruction. It happened, as is frequently true, that the tissues were injured higher up and consequently the flaps of each stump sloughed. Sufficient time was allowed for the proper clearing off of the sloughs and cleaning up of the extremity of the stump before an attempt was made to cover the surface. On the twenty-seventh day after amputation each stump was covered with skin grafts taken from the thighs. In this case the granulations were not curetted. The grafts were applied directly to the granulating surface. Everything did nicely and the raw surfaces were soon covered completely.

Beside the fact of giving this man better stumps because of the skin grafting, he was undoubtedly saved many weeks' time.

The process of grafting directly upon the granulated surface was at that time an experiment with me. The possibility of successfully implanting the grafts directly upon the granulated surface has since been abundantly proven.

I have purposely refrained from the consideration of the results in cases where skin grafting has been practiced upon the ordinary crural ulcers. This course has been adopted for the reason that it is extremely difficult to keep track of these cases after they have been healed. Several cases, grafted as long as three years ago, show no breaking down at the present time. Other cases have come under observation subsequent to complete healing under skin grafts with ulcerated surfaces present. As a rule almost without exception, the part originally grafted was not broken down, the ulcers having occurred at new points in the vicinity of the original ulcer. It seems probable, therefore, that these ulcers will recur in

this class of cases so long as the cause for such breaking down is not removed. Skin grafting can not be looked upon as a radical cure in this class of cases. If the cause or causes of the original condition are not removed, we may reasonably expect ulcerated patches to appear from time to time. Where skin grafting is done for the relief of conditions other than that of leg ulcers, the results have not only been satisfactory but permanent.

THE DEGENERATE EAR.

Read in the Section on Neurology and Medical Jurisprudence, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY EUGENE S. TALBOT, M.D.

FELLOW OF THE CHICAGO ACADEMY OF MEDICINE.
CHICAGO.

Discussing the "stigmata of degeneracy in the aristocracy and regicides," I dwelt with most emphasis on oral and facial stigmata. I now propose to deal with an organ which in the opinion of alienists, biologists and criminal anthropologists, is most affected by degeneracy.¹

Considering the wide range of variation in the external ear in closely related zoological families, such, for example, as the African and Asiatic elephant, this was to be expected. My own experience confirms that of the alienists and criminal anthropologists as to its occurrence in degenerate man.

It has been claimed that deformities are due to pressure by sleeping upon one side or the other and pressure of wearing apparel. This can scarcely account for excessive and arrested development, since most stigmata exist at birth and are exaggerated as the ear develops in size. Such being the case local conditions can in no case produce excessive or arrested development in cases other than those produced by traumatism. This arises from the fact that it is a cartilaginous organ extending from bony base without a bony framework for its support and with very poor blood supply. While it no doubt receives all nourishment necessary, yet its parts are so far removed from the great blood supplies that from any defect in the nerve centers of those which control the local blood supply, or from malnutrition, the parts become materially affected. As a cartilaginous organ the ear has no lymphatics, a fact bearing on the growth of the ear throughout life. That the ear is sensitive to vasomotor changes is verified by the result of extremes in heat and cold, emotional blushing and fatigue.

In dealing with the question, aural embryology demands discussion, since in it are outlined many future changes. Skipping evolution of the ear from the otolith of the fish to the ear of the mammal, human otic embryology alone requires attention. Minot points out that "before the end of the first month there appears around the external opening of the first gill-cleft a series of six tubercles, two in front on the hind edge of the first visceral arch, one above the cleft and three behind it. A little later a vertical furrow appears down the middle of the hyoid arch, in such a way as to mark off a little ridge

¹ I wish here to express my thanks to the following gentlemen for their kindness in allowing the privilege of visiting their institutions and compiling the statements given here: Major R. W. McClanghry, superintendent Illinois State Reformatory, at Pontiac; Hon. Z. P. Brockway, superintendent New York Reformatory, at Elmira, N. Y.; Mr. O. W. Nash, superintendent Cook County Poorhouse; Dr. Clark Gaph, superintendent Illinois Eastern Hospital for the Insane, at Kankakee, Ill., and Mr. Alfred Brisbols, photographer, for the use of photographs of prominent men.

which joins on to tubercle three and descends behind tubercles four and five. The second stage is reached by the growth of all the parts; the fusion of tubercles two and three and the growth of the ridge down behind tubercle five to become continuous with six. After these changes it is not difficult to identify the parts.

"Tubercle No. 1 is a tragus; 2 and 3, together with the arching ridge, represent the helix; 4, the antihelix; 5, the antitragus, and 6, the lobule; the pit between the tubercles, the fossa angularis. During the later part of the second month the ear changes in its proportion somewhat, in the irregular development.

Fig. 1.

Fig. 2.

"The third stage begins at the third month. The upper and posterior part of the concha arises from the surface of the head and gradually but rapidly bends over forward, so as to completely cover the antihelix and the upper portion of the fossa angularis. During this stage in mammals the assumption of the pointed form of the ear commences.

"The fourth stage commences at the fourth month, when the tubercles which are now joined together by cartilages commence to unfold and are complete by the fifth month. Finally the sixth tubercle develops to form the lobule."

This unfolding or development of the tubercles to

Fig. 3.

Fig. 4.

produce the different portions of the ear and make it complete, is not unlike the development of a flower from the bud. By this process may be understood how, if by malnutrition in one tubercle or bud or another, or should there be a larger supply of nutriment in one than another, malformation of the ear would result. If arrest of development of all the tubercles should take place at any period from the first to the fifth month of fetal life, the ear would resemble a semi-developed flower.

The aural deformities that fall under the head of stigmata, or that have been classed as such, affect all portions of the external ear. The helix may be im-

perfect, it may be angular from Darwin's tubercle, it may lack its inward roll, it may be interrupted, the root of the helix may extend inward completely across the concha and in very rare instances it may be bifurcated. The antihelix may be unduly prominent or be insignificant, the scaphoid fossa may extend through the lobule and be double or triple. The lobule may be adherent and sometimes almost absent, thus producing the jug-handle-shaped or so-called Morel ear. It may be exaggerated in size; the whole ear may be misshapen, too large or too small. These deformities may exist in nearly every degree; only when pronounced can they be considered as stigmata. Others have been noted, but their importance as

Fig. 5.

Fig. 6.

signs of degeneracy is very insignificant unless they co-exist with several of those above mentioned.

The normal ear, or rather the ideal ear, for few possess it in its entirety, should have gracefully curved outline, nowhere pointed or angular, have a well-defined helix separated from the antihelix by a distinct scaphoid fossa extending down nearly to the level of the anti-tragus. Its root should be lost in the concha before reaching the antihelix. The antihelix should not be unduly prominent and should have a well-marked bifurcation at its superior extremity. The lobule should be shapely, not adherent or too pendulous and free from grooves extending

Fig. 7.

Fig. 8.

from the scaphoid fossa. The whole well shaped, its proper proportions and size can be inferred from the tables herewith given: In the adult we may say that it ought not to average much over two and a half inches in length and one and a fourth in breadth.

To describe a normal ear would be as impossible as to describe a normal jaw or dental arch. Some eight or ten years ago I collected 3,000 plaster casts of the upper jaw, and in the whole collection no two were found to be alike. If 10,000 or 20,000 casts were presented for examination no two would correspond. This is also true of the human ear. To such an extent is this the case that the two ears of

the same person never correspond either in shape or position, and rarely in size. Again in making an examination for a normal ear two investigators would never agree as to what would be considered as normal. A typical ear as a guide in the study of degeneracy has been described by many writers, G. Ballet, Frigerio, etc. The typical ear, thus regarded, consists of one whose length, width, shape and form represent the average of a large number of ears of apparently normal individuals, the parts of which are all developed in harmony, with graceful curves and outlines.

Frigerio has shown that the normal ear is from 1.95 in. (50 mm.) to 2.34 in. (60 mm.) in length. In an examination of the ear of 356 apparently normal persons, I have found in people over 12 years of age and under 50 years, that the shortest ear was two inches, longest three inches, with an average of 2.50 inches. Narrowest width, one inch; widest, 1.50 inches; average, 1.22 inches. If all structures of the ear can be well developed and in harmony, and should no two resemble each other, it may be regarded as a typical ear.

The chief points in which variations from the normal, and stigmata of degeneracy have been found, are: The auriculo-temporal angle, the position of the ear upon the head, the size, the helix, and antihelix, especially the root of the former, the presence of the tubercle of Darwin, and the shape and development of the lobule.

Like the other deformities, the angle does not denote the criminal alone as claimed by some observers, since frequently just as extreme angles are found among deaf-mutes, dumb, blind, insane, prostitutes, egotists, one-sided geniuses and occasionally among people considered normal. There is this to be said, however, the ear is more prominent at birth and up to the sixth or eighth year than later in life. In other words, the tendency is for the auriculo-temporal angle to become smaller, as the individual grows older. This only shows that the theory advanced by Frigerio that while very few ears are observed at right angles in apparently normal individuals, they will in all classes of degenerates frequently be seen. The percentage among the degenerate classes is greater than in normal individuals.

The different parts of the ear may be well developed while the general shape and outline is the opposite; on the other hand the external outlines may be graceful and pleasing to the eye, while the parts which go to make up the ear may be markedly deformed.

The position of the ear upon the head has been used by neurologists and others as a fixed point in cerebral localization. This can only be approximately correct since the position of the ear varies; in many cases greatly. Not infrequently the ear is found located forward and again back, high or low upon the head. In its relation to the mastoid process and coronoid process there is the greatest deviation. The two ears vary in position in the same individual, one ear often higher and placed more forward than the other.

Thus in an examination of twenty-two skulls by drawing a line perpendicularly through the center of the mastoid process and through the center of the glenoid cavity, it was found that not only did the auditory canal vary from one-fourth to one-half inch in different skulls, but that they differed in the same skull one-fourth of an inch. By placing a square on

the perpendicular line in the center of the mastoid process and allowing the arm to meet the outer and upper border of the glenoid cavity by drawing a line with a pencil upon the skull, the position of the auditory canal can easily be located. Thus it will be seen that the canal varies from one-eighth to three-eighths of an inch in a perpendicular direction. Since this is the case in apparently normal skulls, what must be the disparity in position in degenerates when the two halves of the head are so markedly deformed, or when the ears are situated in the posterior or anterior part of the head, or when the upper border of the ear is an inch above the superciliary ridge when it should be on a line with the inferior orbital foramen? I have observed this great difference in height in seemingly normal persons.

Unlike deformities of other parts of the head, deformities of the ear are always seen at birth, though perhaps not as prominently as later in life. While excessive and arrested development of the different parts of the ear are always congenital, they are not always inherited, since many are the result of excessive or arrested nutrition in utero. These deformities are often seen among idiots and feeble minded. The same causes which produce the one in utero, in apparently healthy parents, produce the other.

The Greek and Roman artists, judging from their sculpture, seem to have had no idea of a normal ear. Either they considered the form and position of the ear of little moment in delineating features and character, or the models used by them consisted of marked degenerates; the latter most probably being the case. Many large men have unusually small ears, and small men unusually large ones, while most present the handle-shaped and degenerate ears. The singularly consistent use Hawthorne makes of the degenerate ear in "The Marble Faun" will be recalled by students of American literature.

Morel described the deformities of this organ fifty years ago; later Darwin, struck by the frequency of a tubercle upon the outer border which has received his name, used this organ as evidence of the "Descent of Man." Still later, the ear has been studied by Giachi, Fere, Spitzka, Launois, Frigerio, Ottolenghi, H. C. B. Alexander and others. These signs of degeneracy consist of variations in size, position and shape of the ear as a whole or in part, and are the results of excessive and arrested development.

Deformities of the ear have been studied in the different institutions for special conditions of degeneracy for comparison with what are considered normal individuals. As might have been expected, different results have been observed by different individuals. One investigator may be an untrained novice, while the other has years of experience and can, at a glance, record all the peculiarities. Such being the case, the percentages may differ materially in final results. Only by comparison of the results of different scientists can a just average be obtained.

The illustrations here presented for consideration are those of typical cases, not extreme conditions. There are many degenerates in every class who possess excessive and arrested development of each of the different parts of the ear, and in this manner marked deformities are produced; in some cases exaggeration of parts, in some, arrest of parts. Figs. 1, 2 and 3 illustrate a long, medium and short ear.

The longest ear observed by Frigerio was that of a woman convicted of complicity in uxoricide. The left

No.	Name.	Age.	Method.	Time. Minutes.	No. M.A.	Spur, ridge, crest.	Effects—Remarks.
1	Mrs. T.	46	Monopolar.	18	18	Cart. spur on right side septum.	At the end of ten days the spur was disintegrated leaving a smooth surface covered with healthy membrane.
2	Mr. J. P.	28	"	20	18	Bony crest right side septum.	First treatment reduced crest some. Second treatment (one week later) 15 m.a. 15 min. reduced crest enough to overcome stenosis.
3	Mr. W. H.	24	"	25	18	Horiz. $1\frac{1}{4}$ in. bony ridge right side sept.	Fainted at end of ten minutes; placed him in reclining position and continued 18 m.a. for 15 min. without further inconvenience. One month later ridge gone and membrane intact.
4	Rev. L.	25	Bipolar.	12	15	Cart. ridge left side.	Two weeks later edges of ridge remaining were removed with a chisel. This required as much work and skill as an original operation with a chisel.
5	Rev. L.	25	"	13	15	Cart. spur left side.	Ten days later spur much reduced and membrane intact. Spur was quite small and of soft cartilage.
6	Miss G.	30	"	12	15	Cart. spur left side.	Large flat needle used at base of spur. At end of one week, spur was much reduced and membrane intact.
7	Mr. J. R.	26	"	15	15	Cart. and bony ridge left side.	Eleven days later ridge gone but there was an offensive odorous discharge from seat of operation. Passed probe one and one-half inches back between walls of septum. Twenty gr. argent. nit. checked necrotic process in three weeks.
8	Mr. L.	29	Monopolar.	13 27	27 20	Ant cart. spur left. Post. rdg. bone.	A cathodal needle was inserted into each growth, a large sponge electrode being held in the hand of the patient. At end of thirteen minutes needle was removed from ant. spur, in twenty-seven min. from post. ridge. One mo. later ant. S. gone, post. R. reduced.
9	Miss E.	20	Bipolar.	20	20	Large spur left side. cart. and bone.	After two weeks, spur gone and membrane intact.
10	Miss E.	20	"	12	15	Med. cart. spur right side.	After two weeks, spur gone and membrane intact.
11	Mr. E. S.	26	"	20	15	Cart. spur right side.	For fifteen days sloughing with foul odor; no perforation. At end of one month healing complete. Result good.
12	Mr. E. S.	26	"	13	13	Small cart. spur left side.	At end of two weeks spur was gone. No ill result.
13	Miss P.	21	"	16	14	Large cart. right side.	At end of two weeks spur was gone. No ill result.
14	Mr. C. W.	18	"	18	15	Cartilaginous ridge on right side septum.	Negative needle inserted one inch into ridge. Positive into crest of ridge. At end of first week ridge much reduced.
15	Mr. F. R.	50	"	20	15	Very large cart. spur right side.	At end of second week spur much reduced. Formerly there was great stenosis, now breathing channel was clear.
16	Mr. J. M. B.	25	"	20	15	Horiz. ridge, cart. and bone $1\frac{1}{4}$ in. long, left side.	Negative needle inserted one inch into ridge, positive inserted into crest. After three weeks ridge almost gone, stenosis greatly relieved.
17	Rev. S.	45	"	14	15	Horiz. cart. ridge on right side of septum.	One month later ridge almost gone, membrane intact.
18	Mr. C. S.	32	"	15	10	Horiz. cart. rdg. (ant.) $1\frac{1}{2}$ in. long left side.	Two negative needles used, one inserted into the anterior, the other into the posterior part of ridge. After three weeks anterior part gone, posterior reduced.
19	Mr. V. H.	24	"	16	15	Cart. spur on left side of septum.	At end of second week spur gone and membrane intact.
20	Mr. E. S.	20	"	15	13	Cart. spur right side.	Spur only partially removed, a second operation with a chisel being necessary for its complete removal.
21	Miss P.	21	"	14	12	Small cart. spur on left side.	At end of second week spur gone, membrane intact.

* Cases Nos. 1, 2 and 3 were reported in paper No. 1.

ated at the anode (positive pole) and hydrogen at the cathode (negative pole). If this process be continued the entire amount of water in the vessel will be decomposed, and in its stead will be two parts of hydrogen by volume and one of oxygen. This is a simple illustration of the electrolytic action of electricity when applied to a simple electrolyte. If the substance to be decomposed or disintegrated is more complex in its chemic composition it will undergo the same molecular disintegration, but it will be more difficult of demonstration.

When a direct (galvanic) current is passed through animal tissue it is more or less disintegrated, its molecular, its cellular structure is broken up in the immediate vicinity of the poles. Near the anode (positive pole or electrode) oxygen, chlorin and acids are accumulated, while around the cathode (negative pole or electrode) hydrogen and alkalies are accumulated. There is, no doubt, some interpolar change in the tissues remote from the poles, but it is difficult of demonstration. An inflammatory action is excited, osteoclasts are left in the broken-down tissue and absorption takes place through their agency. Where a larger area is entirely cut off from blood supply it sloughs without absorption. The electrolytic power of the current is in proportion to its density, hence, it is usually applied by means of needles as the active electrode, the indifferent electrode being from a few to a hundred square inches in area, according to the quantity of current needed in the case under treatment. In bipolar electrolysis both poles, usually needles, are introduced into the tissue to be destroyed. It should be remembered that electrolysis does not necessarily mean the caustic destruction of tissue, but rather the chemic disintegration of it.

There is a primary and a secondary electrolytic

action to be taken into account. By primary electrolysis is meant the chemic dissolution of the elements composing the tissue; by secondary electrolysis is meant those changes which occur, owing to the presence of the liberated chemicals already referred to. The primary action takes place during the time the current is passing through the tissues, while the secondary action occurs so long as the newly liberated chemicals (hydrogen and alkalies, or oxygen and acids) remain free in the tissues and the osteoclastic absorption is in progress. In some cases it continues active several days. The characteristic reactions occurring at either the positive or negative pole is chiefly due to the peculiar chemic products formed at the respective poles. At the anode we should expect the tissues to be hardened, coagulated, owing to the presence of oxygen and acids about it. At the cathode we should expect the tissues to be softened, liquified, owing to the presence of alkalies there. A moment's consideration will suggest the wisdom of this law, for a vascular growth needs in addition to the disintegration of tissue to shut off the blood supply of the part, so as to prevent rapid repair of the part, while in fibrous tissue the blood supply is poor and a softening of the tissues is needed to favor absorption through the medium of the phagocytes and circulation. Hence, vascular growths are most effectually treated with anodal electrolysis, while firm fibrous growths are best treated with cathodal electrolysis. In some conditions (notably bony and cartilaginous growths) it is indifferent which pole is used locally, or it may be found expedient to use both locally, in order that the current be confined more perfectly to the offending tissue.

The advantages of the bipolar method for operations in the nose are: *a*, the current is limited to

the offending tissues and shock from diffusion of current to brain is avoided; *b*, perforation of the nasal septum is avoided as the current is limited to a field superior to the plane of septum, *i.e.*, to the path between needles in the growth; *c*, the method is simple and less painful than the monopolar method.

Specially devised needles may be used, or in most cases extra large sewing needles answer every purpose. Moure¹ has designed a series of double needles to be used in the base of spurs and ridges, whereby he claims superior results are obtained as the current is more uniformly distributed through the growth, thereby favoring its complete removal with a minimum quantity of electric force. All my operations were done with single needles except No. 18. The part of the needle not imbedded in tissue should be insulated with varnish or small rubber tubing to prevent destructive action to inoffensive tissue.

The outfit needed to do electrolysis of bony and cartilaginous spurs and ridges of the nasal septum must embrace the following: *a*, a source of electric energy equal to twenty-five LeClanche cells—a properly reduced and guarded Edison current may be used; *b*, a reliable rheostat, the Massey current controller answering every purpose; *c*, a reliable milliamperemeter. It would be folly to attempt to do electrolytic work without accurate measurement of the electric energy employed. To depend on the number of "cells turned on" is as absurd as to tell a patient to take ten pills without regard to the quantity of medicament each represents. Cells used in medical batteries have an electromotive force ranging from 1 to 2 volts, and the resistance of the various tissues of the body varies all the way from 2,000 ohms to 500,000 ohms, hence there is no way of estimating the quantity of current passing through the body except to measure it with some reliable instrument. The quantity of electric energy required to disintegrate such growths as are of common occurrence in the nose and throat is from 2 to 30 m.a., according to the size of growth and kind of tissue composing it.

In my first paper² it is implied that I was the first American observer to write upon this subject, but I now freely accord Dr. James E. Newcomb, New York, precedence in the field. In the *Medical Record*, Aug. 5, 1893, he wrote under the title, "Electrolysis for the Relief of Certain Morbid Conditions of the Nasal Septum." He gives an admirable review of the literature to that date with a report of two cases. Since then, there has been little that is new, except some slight modifications in needles and the adaptation of the Edison current to nasal electrolysis by Dr. Casselberry.³ He takes the position, in an article read before the American Laryngological Association, at Rochester, that bony growths will not yield to the electrolytic action of the current, contrary to continental observers and also contrary to my own observation.

I present herewith a tabular report of twenty-one cases in private practice, from which I arrive at conclusions as to the propriety of resorting to electrolysis for the removal of septal spurs and ridges.

These cases were all well-nourished, healthy people. An equal number of dispensary cases treated in the same way would, no doubt, show less favorable

results. While the results are quite favorable in most cases, the fact still remains that as a method it is neither so simple nor so sure as others at our command. I quite agree with Dr. Bresgen⁴ that its scope should be limited: *a*, to those cases in which it is impossible to carry out the usual surgical treatment, either on account of weakness or other disability; *b*, those cases in which more radical measures are refused; *c*, that electrolysis is not, nor can it ever be, a therapeutic measure which can be used by other than experienced specialists, because when carried out by unskilled hands it can only lead to disaster. Dr. Bresgen was supported in his conclusions by Drs. Hajek, Stoerk, Heymann and Chiari.

I will add the further conclusions: *d*, cartilage yields more readily than bone; *e*, an osteoma is more easily removed than normal bone, because being an abnormal growth it is an irritant and is therefore more unstable, requiring less irritation to cause proliferation of osteoclasts; *f*, only growths of minor size are successfully treated by electrolysis, those of major size being only partially removed; *g*, large growths, especially those with a wide base, should be attacked with double needles at base and single needle at apex; *h*, perforation and sloughing will result from the use of too much current, or from a prolonged use of a moderate one (see case No. 7); *i*, all cases should be thoroughly cocaineized by placing a pledget of cotton saturated with a 10 per cent. solution of hydrochl. cocain over the part to be operated on, and leaving it there for eight minutes.

THE TREATMENT OF TRACHOMA AND TRACHOMA SEQUELÆ.

Read in Part at the Annual Meeting of the Tri-State Medical Society, at St. Louis, April 3, 1895.

BY CHARLES H. BEARD, M.D.,

SURGEON TO THE ILLINOIS CHARITABLE EYE AND EAR INFIRMARY; OCULIST TO THE EMERGENCY (PASSAVANT) HOSPITAL. CHICAGO.

Trachoma cases come to us for treatment not only in all stages and states of active disease—such as acute, sub-acute and chronic—but also after the affection has worn itself out; been consumed by its own fire, so to speak, and we have to do only with its effects; and every phase of the morbid process, every attendant complication and, lastly, every resulting defect of the lids or eye, calls for some particular method of handling.

In view, therefore, of the prevalence of trachoma, or granular conjunctivitis, or granulated lids, or what you will, in the three States represented by this society, especially in Illinois, and having, through my connection with the Illinois Charitable Eye and Ear Infirmary for the past eight years, been afforded admirable opportunities for observation along this line; moreover, in view of the fact that the disease is peculiar to the very class of sufferers who can not, as a rule, most easily consult the oculist and comes, perhaps, oftener than any other ocular affection within the province of the general practitioner, I could think of no more fitting subject to bring before you.

To the point then, and briefly: As to the acute stages of trachoma the treatment must be mainly that of septic conjunctivitis in general. The free and constant use of antiseptic solutions, as baths, douches

⁴ Journal of Laryngology, Rhinology and Otology, Jan. 1895.

and instillations; the application over the closed lids, and for only three to ten minutes at a time of intensely hot water, the sparing use of atropin for its quieting effect, and occasionally when the deeper parts of the eye, such as the iris, become involved, the putting of leeches to the temple. As an all-around disinfectant remedy nothing quite equals a solution of the bichlorid of mercury. For a douche or instillation its strength should not be less than 1-10,000 nor more than 1-2,000; as a strictly localized application, however, one may with safety and to advantage use solutions varying from 1-500 up to 1-60. Second in importance only to sublimate is the nitrate of silver, either in solution or in substance. I may state, once for all, that in the use of these salts not so much depends upon the strength of the solution as upon the method and tact with which it is applied. A nicely sharpened pencil of lunar caustic may by deftness and caution be made to give the mild effect of a 2 per cent. solution of the same. By your leave I will explain my manner of applying these strong solutions to the conjunctiva. Of silver I rarely use less than sixty grains to the ounce of distilled water, or perhaps what is a still better medium, a 4 per cent. solution of boric acid in distilled or boiled water. The nitrate of silver dissolved in this gives a clearer and more stable solution than when dissolved in water alone. Being seated in front of the patient or, if a child, holding its head tightly between the knees while the body and hands are held by an assistant, the eyes are washed externally with absorbent cotton wet with warm boric acid solution, special care being taken to cleanse the cilia and canthi, after which the lids are everted, sponged off with absorbent cotton dipped in boric acid solution and tightly wrung, for dry cotton should never touch the eyes. A small delicately pointed brush is made by winding absorbent cotton on a silver probe. Camel's hair brushes I consider an abomination. If one could keep them absolutely clean and have a separate one for each patient they would be bother enough, but this is impossible, while absorbent cotton is not only always clean and ready, but is actually a better vehicle. Making sure now that the exposed conjunctiva is freed from moisture by sponging, the brush is dipped into the strong solution, whether it be of silver or sublimate, touched to the lip of the vial so that at the moment of coming in contact with the lid it will not give off a drop to spread and do injury to the unaffected parts. And here is just the point, to strictly localize the effect.

No doubt much harm has been done in the treatment of these cases by the slipshod manner of using caustic remedies; by allowing a solution of silver, for example, to run down over the cornea, destroying its epithelial protection, thus giving better chance for infectious ulcers; again by indiscriminately touching the whole of the exposed conjunctiva, diseased and normal portions alike, thus aiding the malady itself in the destruction of tissue and favoring greater cicatricial contraction afterward. Whether we use brush, pencil of lunar caustic or crayon of copper, I repeat, it should be sharp-pointed and the granulations should be gone over therewith much as an artist goes over his nearly-finished painting putting in the high-lights. Sufficient impression must be made at each point where the remedy is applied to cause the appearance of a decided coagulum—dense white if silver, grayish if sublimate or copper. Im-

mediately after this, comes copious douching of the whole conjunctival sac with very warm saturated solution of boric acid; dropperful after dropperful is poured on the membrane, flooding cornea and all, the patient holding a hard-rubber pus basin beneath the chin to catch the overflow. I have found that the warmer this douche can be borne the better. One's patient is more comfortable after the treatment.

Lastly, the excess of moisture is again sponged away and one drop of a 4 per cent. solution of cocain, containing six drops of carbolic acid to the ounce, is let fall upon the everted upper lid. The eyes are then carefully wiped externally with wrung-out cotton to keep the patient himself from employing his own means and materials for doing it; indeed he is told to let the eyes severely alone. Many trachoma cases, both acute and chronic, will come with photophobia and spasm of the orbicularis, which, aside from being bars to progress in treatment, cause complications such as pannus, conical cornea, trichiasis and entropion.

It was for a long time believed that entropion was solely due to the contraction of the conjunctiva and warping of the tarsi from connective-tissue degeneration; it is now known, however, that an important factor in the production of this deformity is prolonged blepharospasm, especially of the tarsal and border fibers of the orbicularis. Through its influence the posterior angle of the free border of the lid is absorbed, whetted away, as it were, and the anterior angle with the cilia brought down in contact with the eyeball.

Our first care then, where exists dread of light and spasm of the orbicularis of the lids, should be to remove these conditions. The former will yield to systematic exposure of the cornea to bright daylight. If the patient has resolution enough he can often be prevailed upon to keep his head erect and his eyes open until they will tolerate the light; if he can not or will not try to do this, cocain may be instilled, a blepharostat put in, and the face directed toward a well-illuminated window. This done for a few minutes daily works wonders. Best of all, however, for both conditions, is a well-made canthoplasty, together with free division of the external canthal ligament.

Where there is excessive lymphoid infiltration of the conjunctiva, be it contained in discrete granulations or trachoma bodies, or whether it be distributed profusely beneath and in the swollen papillæ, thanks to the man who invented squeezing-out¹ forceps; the process of treatment in such instances has been tremendously shortened by the expression of the infiltrated portions. Here is a pair I have had made of tortois shell, a material that resists the action of the strongest antiseptic, and by its elasticity prevents undue laceration in the squeezing procedure. The operation of excising the retro-tarsal fold or fornix of the conjunctiva for the cure of granulations has always struck me as being a little too heroic, since great loss of this membrane, particularly where such loss would tend to restrict the movement of the eyes and lids, is precisely what we wish to avoid.

Yet there is a time for excision of the granulations, viz., when the hypertrophy of the papillæ has gone to the extent of forming hard knob-like tumors in more or less advanced stages of connective tissue degeneration over the tarsus and at its upper border. These act like so many foreign bodies and by their

¹ Suggested by Mandelstaum in 1883, and first practiced in America by Dr. F. C. Hotz, of Chicago, in 1886.

continual rasping do great damage, especially to the cornea. Their indifference to the laying on of ordinary medicaments is supreme; even the oft-repeated and prolonged rubbing of them with a bit of sulphate of copper but serves to give them a little polish. Hence in dealing with these it is my custom to evert the lid, put on a drop of cocain solution, and with delicate, sharp scissors, curved on the flat, trim them short off.

As to corneal complications, they are as a rule purely secondary and do not require special attention. At times, though, an ulcer will become too large or threaten to perforate, requiring vigorous antiseptic treatment and, if encroaching on the posterior layer of the cornea, eserine to lower the intra-ocular tension, and a roller bandage to give outward support. Sometimes, too, blood vessels will remain over the center of the cornea, interfering with vision and disfiguring the eye, even after the original disease has disappeared. To cause their absorption one has but to incise the tissues immediately surrounding the cornea in a complete circle and clean down to the sclera, retract them somewhat and scrape the bottom of the furrow well with the convex edge of a sharp scalpel.

Passing now to those sequelæ of trachoma that call for surgery of the lids, we will consider only what goes by the rather comprehensive name of entropion. This may consist mainly in a slight warping or incurvation of the tarsus from the deposit of scar tissue in a more or less pronounced horizontal groove along its inner face, the free border being fairly well preserved, and only a few eyelashes resting on the cornea; in which event a well-executed Hotz operation will suffice to set all to rights again. But by far the greater number of the cases, as we find them, will have a much more aggravated condition. In many the conjunctival sac will be shrunken until both upper and lower fornices are obliterated—the tarsi so atrophied that their transverse measurement is only half, or less than half, the normal, having a deep groove within, and a decided ridge without, and the free border of the lid worn down to a very thin edge just at the point where the lashes emerge from their follicles, and the lashes themselves all inside the palpebral fissure, and all resting on the eye-ball. There will be more or less over-tension of the orbicularis, as also photophobia, the last from the corneal irritation. Experience has taught that, in cases so extreme, a Hotz operation alone, no matter how pronounced the primary effect, will not give permanent correction. In short, each distinct, morbid feature, as enumerated above, must be met by a separate surgical measure, and each measure made to give its maximum effect. To replace the inner angle of the free border and, to a degree, the atrophy of the conjunctiva as well, a graft of mucous membrane is taken from the lip and placed just back of the cilia; with the Hotz operation is combined a counter-grooving of the tarsus, and for the relief of lid-tension the border fibers of the orbicularis muscle are excised (not the muscle of Riolan, for this would be impracticable), and canthoplasty, with thorough cutting of the external canthal ligament, is done. Moreover, to insure the best possible and most lasting result all of these operative procedures must be resorted to at one and the same sitting. Were the canthoplasty done to-day, the graft put in to-morrow and the Hotz operation made the day afterward, our object would not be at-

tained. I have seen many instances of failure in the results of these operations, but never one of permanent over-correction. In a number of my own cases, temporary ectropion has occurred, but in none has it remained. Indeed, we might even strive with advantage, to produce slight eversion of the operated lid. With your permission, I will describe the operations as made in exaggerated cases; not because I have anything new to offer, but because, having given much attention to the technique of this particular surgery I desire, for the first time, to give details. Patients are prepared for the operation by a few days of hospital regimen; baths, clean clothing, antiseptic eye-washes and eye-douches. At the moment of operating, the eye and its appendages are most thoroughly and carefully cleansed; the same, as to hands and instruments. Ether is usually given, though many prefer to stand it without; cocain, however, being freely instilled at the site while the instruments are being used. This first step in the combined operation is the making of the canthoplasty, and the cutting of the external canthal ligament. For this the only instrument used is a pair of straight, strong scissors with very blunt points. Standing behind the patient's head the lids are gently pressed apart, one blade of the scissors introduced behind the outer canthus as far as it will go without using force, and as free division of integument and conjunctiva made as can be done at one snip. Then the lid is taken between the thumb and finger, by pulling the external canthal ligament is put upon the stretch and, on putting the scissors into the incision with the blades closed, can be readily felt. One snip also serves to cut it, when the lid at once gives way from its support on that side, as detected by the thumb and finger holding it. The sutures here, which complete the canthoplasty, are left till next to the last step. Next thing, we make the incision just back of the cilia to relieve the mucous graft. Apropos of the tissue here employed, there was a time when I used fine-textured skin, such as exists behind the ear, but having had one case in which a large ulcer came on the cornea just under the graft, apparently due to the fact that the secretions of the lids and conjunctiva failed to moisten the piece, as there were no hairs in it to scratch, and it had to be excised and mucous membrane substituted, before the ulcer would heal. For this incision the only instrument is a small, very sharp scalpel, with great convexity of edge near the point. The lid is well everted and held thus by the fingers alone, not by fixation forceps, for they do too much traumatism. The taking of the first step (*viz.*, the canthotomy) in the operation makes the second an easy one. A rather deep incision is made extending about the whole length of the free border, avoiding the punctum, hugging the conjunctival and not the tarsal side, and observing well that all the hair follicles are in front. The object in making this cut at this stage is to give time for bleeding to cease in time for the last step, *viz.*, the insertion of the graft. The third step is the Hotz operation—a most efficient feature, and too well-known a procedure to require a description. I would like, however, to call attention to two or three points in this connection. The incision through the integument and orbicularis is often made too far from the free border. In this, one should be governed by the width of the tarsus, since it is the "stiffening," as tailors put it, across which the lower flap (we are speaking now

tially. It becomes doubly important that the weak of the upper lid) must be tightly drawn in order to turn out the lashes. Moreover, to get the full effect, this lower flap must be dissected down to the free border, or until we see the cilia stretching across the bottom of the incision like stitches of thread in a seam, being cautious enough not to cut a buttonhole through, and all the border fibers of the orbicularis, that is to say, all those fibers of the palpebral portion that lie near the free border, must be excised. The next step is the grooving of the outer, or convex, side of the tarsus if the latter be much warped. Then, as to the placing and tying of sutures, I was taught, I do not know by whom, but certainly not by Dr. Hotz himself, that the second puncture of the needle carrying the suture was in the tarsus. Instead, it is infinitely better, and was undoubtedly the originator's idea, to utilize the full breadth of the tarsus to stretch the flap bearing the cilia across, and to pass the needle in just *beyond* the convex border of the tarsus. And in tying the thread, after the first turns are taken in it, the lower end is given to an assistant while the operator holds the upper, when, with the other hand, and by the aid of forceps, the edge of the lower flap is drawn up and set in contact, and held at the point where the suture plunges into the deep fascia constituting the ligament of the tarsus, when the knot is drawn tight, surgeon and assistant drawing together, and completed. Then come the sutures to make the canthoplasty; and lastly, the cutting and putting in of the graft. The lower lip is everted by the fingers, washed with warm boric acid solution, and cocaine dropped on. To remove the piece I roll the lip around the ball of my middle finger, and with the same scissors used for the canthotomy, excise at one cut a long ellipse of the mucous membrane, sufficient to fill the incision in the free border of the lid. Dip it in the warm boric acid solution and lay it over the left thumb nail, face downward, and with small, curved scissors, trim off all the adipose and as much of the sub-mucous connective tissue as is practicable, and again immerse it in the warm boric acid solution. The incision which is to receive the piece is now spread wide open and the graft laid in, it goes without saying, flatwise, not edgewise, and with the epithelium outward. Small sponges with thin edges, made by wringing small bits of absorbent cotton out of boric acid solution, are delicately applied round about the border of the graft for a few moments to drink up the ooze of blood and other moisture, the lid being held everted the while; after which the eye is closed and a borated dressing is put on, fixed by a mosquito-netting bandage, applied wet. No sutures are used either in lid or lip. The dressing should be removed after the first forty-eight hours, then daily three or four times, for if the lids are left exposed too soon the grafts become dry and hard, much to their detriment.

605 Venetian Building.

SOME MECHANICAL PROBLEMS IN THE OPERATIVE CURE OF INGUINAL HERNIA.

Read before the Medical Society of the Missouri Valley, Council Bluffs, Iowa, Sept. 19, 1895.

BY B. B. DAVIS, M.D.
SURGEON TO IMMANUEL HOSPITAL,
OMAHA, NEB.

It is customary to think of the abdominal viscera as making unrestrained pressure in every direction in their efforts to escape from the cavity in which they are enclosed. If this were literally true, hernia to the extent of total disability would be the rule. In the normal condition the relationship is such that when the omentum, the small intestine or the large intestine has pressed about so far in any given direction, it can go no farther, not because of the resistance met in front, but because of the restraint offered by the mesentery, the mesocolon, or other attachments. This restraining force does not manifest itself by a sudden pull like the jerk when the end of an elastic cord is reached, but by the gentle traction of an elastic tether, which causes the organ to glide away from the danger point over the slippery peritoneal surface.

From these considerations the inference is natural that because A has a hernia and B has not, it does not prove that A's abdominal wall was originally weaker than B's, or that A's deep ring was more open or more distensible. But it is fair to infer that A's mesentery or mesocolon is abnormally long or abnormally attached; or, if the omentum be the *persona delicta*, that this apron is too long, or too heavy, or its attachments above have descended from either dilatation or displacement of the stomach. In the event of none of these abnormalities being originally present, A has probably been in the habit of overloading the alimentary canal by eating too much, or has been a victim of constipation, or his work has been such as to subject him to frequent and severe strains. Any of these influences may have brought about in an artificial manner the conditions favorable to the production of hernia.

If the above are the correct etiologic factors, when the question of the operative cure of a hernia is considered, the surgeon must (1) and preferably, remove the original cause, or (2) make the abdominal wall at the site of the rupture stronger than nature made it. Unless one or the other of these conditions is met, efforts towards cure are bound to be followed by disappointment on the part of the surgeon and the disgust of the patient.

1. The first requirement can seldom be met except in a slight degree. It would not be practicable to put a tuck into a too long mesentery or mesocolon; but it may be possible to temper gluttonous habits, correct constipation, or induce a patient to follow an easier occupation. Should the contents of the sac be omentum it is a good plan to curtail its length by ligating and removing the extruded portion. I have practiced this expedient in several cases and have been pleased with the result. De Garmo not only removes what omentum he finds in the sac but draws down as much more as possible, ligates and removes it. This procedure comes very near fully meeting the condition.

2. But it must be admitted that in the majority of cases the first condition can be fulfilled only par-

A MEDICAL GENTLEMAN.—A medical gentleman always recognizes that it takes money to publish a good medical journal and that as a rule the better it is the more money it costs. He does not fly into a passion when he receives his reminder in the form of a bill for subscription, but as he hopes that his patrons may pay him, he promptly sends the amount to his publisher, *tuto, cito et jucunde*.

point in the abdominal wall be made stronger than nature made it. Until very recently this had not been very generally accomplished. In a paper before the American Surgical Society, in 1890, no less an authority than Bull asserted that he had never seen a case that had remained cured five years after having been operated upon.

So much for hernia in general. The difficulties with which we have to deal and the generally unsatisfactory results of operations for the cure of inguinal hernia need no further comment than a reference to the myriads of "new" and "improved" processes which from time to time have been heralded to the medical world only to give place to a method still newer in the next issue of the journals. A disability so frequent, so troublesome and so dangerous has been deemed of sufficient importance to command the attention of hundreds of workers who have given to the subject their best thought. Until very recently no operation had been devised in which the percentage of permanent cures was great enough to make any surgeon very sanguine. When a sufferer consulted an honest medical man he was likely to be told to content himself with the use of a truss, however unsatisfactory, and cautioned against any form of surgical operation as too dangerous and uncertain.

Since it has been made possible to perform such operations with very slight risk to life or danger of wound infection, the efforts to solve the mechanical problems that enter into a cure of hernia have been redoubled. From St. Petersburg to San Francisco and from Italy to the North Cape surgeons have been at work trying to evolve a way to strengthen a place in the abdominal wall which nature has left intrinsically weak.

The weakest point is usually at the site of the deep ring. Although the spermatic cord is surrounded here by a strong muscular and tendinous border there is often space for a small piece of omentum or intestine to insinuate itself by the side of the cord when a cough or anything else which increases intra-abdominal pressure will stretch the ring and increase the space by the side of the cord, putting everything in a more unfavorable condition to bear the next strain. Repeated stretching in this manner is doubtless the usual precursor of the sudden "giving away" by which the average patient describes the origin of his rupture. This "giving away" I take it is only the final step in a process which has been going on for a considerable time. There are occasional cases in which a sudden very intense strain has produced the hernia, the ring not having been stretched and weakened before, but I believe such cases to be very rare. These remarks do not, of course, have any reference to congenital hernia, whose formation is so well known as to need no explanation here.

Numerous methods have been devised for the disposal of the hernial sac. It has long been the orthodox belief that the sac must be so disposed as to leave a smooth surface or a convexity, that the impact of the abdominal contents during a moment of increased intra-abdominal pressure, may not find a depression at the place of exit of the cord. This has always seemed to me to be making a great matter of what is really an unessential. It makes little difference what disposition is made of the sac; within a few weeks the peritoneal surface will be smooth.

The important point is that there shall be no infundibulum left external to the peritoneum. If such

an infundibulum exist, it matters not how smooth the peritoneum may be, it will soon be invaginated into the depression, the thin, distensible peritoneum presenting very slight resistance to pressure. This furnishes a useful hint when it comes to treatment. The stronger structures external to the peritoneum must be well drawn together and the cord must pass through as narrow an opening as is consistent with continued function of the cord. This gave rise to the practice of closing the deep ring external to and above the cord. But one of the weak points of such operations arises from the condition in which the transversalis fascia is left. This structure is one of the strongest elements making up the abdominal wall. In old and large hernia it has become much stretched. When the cord is simply pushed backward and the tissues more external are closed over it the overstretched transversalis fascia is left untreated and it presents almost an open door for a new hernia. This condition of the transversalis fascia is doubtless what lead Bassini and Halstead to see the need of a stronger wall posterior to the cord. The construction of a new canal with a strong and firm posterior wall was evolved and the operation for the cure of inguinal hernia is now upon a secure basis—relapses being very few.

A brief comparison of the relative excellences of the Bassini and the Halstead operation may be profitable. The inference is often made that, if Bassini's operation is radical, Halstead's is still more radical, and therefore, if the former is effectual, the latter must be still more effectual. This is a plea frequently made in favor of the Halstead method. Whether there is anything in this specious reasoning let us see.

The statistics of both operations are excellent. Bassini's latest reports show a total of 536 operations with no deaths and only 15 relapses; and Coley reports 160 operations done by his modification of the Bassini operation—using kangaroo tendon for the buried sutures—with one death from double pneumonia on the fifth day and three relapses. Halstead's statistics seem equally good though lacking the number of operations performed.

Admitting that from a statistical standpoint there is little to choose between the two methods there seem to be a few valid objections to the Halstead operation which are less apparent in the operation of Bassini:

1. With the carrying of the incision through the deep muscles outward from the deep ring for the purpose of transplanting the cord, the operation is made a true laparotomy, and such an incision carries with it all the inherent dangers of an abdominal hernia to which every laparotomy is subject.

2. The new ring of Halstead is made of normal muscular tissues and would not seem to be the ideal structure for a ring. It would be wanting in firmness and be too easily distended when impinged upon. When the cord is simply carried to the outer margin of the natural ring and the ring is closed as closely as possible from the inner margin, as after Bassini, the margins of this smaller ring are already smooth and almost tendinous and are much less distensible than ordinary muscle.

3. When the cord passes directly through the deep muscles and also through the aponeurosis of the external oblique, as Halstead does it, it must then bend at right angles downward and inward. Just at the

bend there must be decided pressure of the dense aponeurosis which can not fail to produce occasional destructive pressure upon the spermatic cord. The same objection has been raised against the Bassini operation and some cases of atrophy of the testicle have been noted. If this accident can result when the bend of the cord is made over the softer tissues it is certainly much more likely to occur after the Halstead method.

4. An objection often made to the Halstead method is that it places the cord so superficially that it is exposed to dangers from contusions. Although I do not believe this would often happen there can be no question that the criticism is valid.

5. By uniting the aponeurosis of the external oblique over the new canal, Bassini forms a solid point of resistance over the deep ring. In order for a new hernia to form an opening must first be forced so large that the viscera extruded can turn at a right angle underneath the firm aponeurosis—a thing very unlikely to happen. In the Halstead operation, the new canal passing directly through the whole thickness of the abdominal wall, there is no hindrance to the viscera pushing their way directly through, if once the slightest infundibulum forms at the inner end of the canal. Any one who will for a moment think how easy it is to separate the fibers of the external oblique when they once begin to separate, can not fail to see that this aponeurosis, in order to do effective service, must be intact. An opening through it large enough to permit the exit of the cord introduces an element of weakness which does not obtain in the Bassini operation. That the aponeurosis of the external oblique serves as a buttress and adds greatly to the strength of the wall can be fully appreciated when one calls to mind the frequency of direct inguinal hernia, which occurs at the superficial ring, the point where the underlying tissues are not re-inforced by the aponeurosis. Kocher claims that the main cause of relapse is the overstretched condition of the aponeurosis and the chief distinguishing feature of his operation is to draw this structure taut by means of sutures. Here we have a high authority for the statement that the aponeurosis does serve as a buttress. In doing the Bassini operation I believe it is advisable to suture the aponeurosis over the cord as firmly as can be done without dangerous tension. This can best be done by inverting the edges.

6. Finally in case of relapse after the Halstead operation the condition is likely to be worse than after the Bassini. If the hernia recurs after Halstead's method the skin and superficial fascia offer no opposition to the hernial contents. And as any one can see, if the external oblique fibers once begin to separate, they will separate easily and there is no limit to the size to which the relapsed hernia may attain. After the Bassini operation, if a relapse occur, the intact aponeurosis will act as a check and will offer a favorable condition for the use of a truss.

There are one or two modifications of the Bassini method which seem to me will improve its usefulness. One of them is the practice introduced by Halstead of ligating and excising superfluous spermatic veins, especially if varicocele or anything approaching varicocele be present. The cord can thus be much reduced in size and with it the caliber of the canal.

Another decided improvement is the use of kanga-

roo tendon for buried sutures, as so ably practiced by Coley. Marcy, of Boston, has shown that kangaroo tendon when buried in the tissues is absorbed at the end of two or three months; and Bosse has thoroughly investigated the healing process of tendinous tissue, finding it complete at the end of ten weeks. From this showing there can be no doubt that kangaroo tendon is the ideal suture, being superior to silk, catgut, silver wire, or silkworm-gut.

I have no hesitation in pronouncing the Bassini operation, slightly modified, the best yet devised for the cure of inguinal hernia in the male. The rationale of the method is scientific and the practical results all that could be expected of any operation. Following is a brief résumé of the steps of the operation as I am in the habit of performing it:

After one or two days of liquid diet, the alimentary canal having been thoroughly emptied, and the field of the operation having been shaved and scrubbed a few hours before, an incision is made, just above and parallel to Poupart's ligament, extending from an inch external to the deep ring, to the spine of the pubes. This incision is carried directly down to the aponeurosis of the external oblique and the tissues retracted slightly in order to bring the white aponeurosis into good view. Next the fibers of the aponeurosis are separated, the separation extending from the superficial ring to a short distance external to the deep ring. The aponeurosis is then loosened for a half inch to an inch above and as far as the attachment to Poupart's ligament below and the borders are held aside by retractors.

The cord and sac are now laid bare and the sac separated well down to the abdominal peritoneum. The sac is then opened, and if the contents be omentum this structure is ligated and cut off; if the contents be intestine it is reduced. The sac is next drawn well out, twisted, tied with catgut ligature, and cut off. The cord is raised, superfluous veins ligated and excised and the remainder held out of the way by an assistant, using his finger or a dull retractor. Kangaroo tendon sutures are used to unite the internal oblique, transversalis, and transversalis fascia to the posterior surface of Poupart's ligament. The internal suture should be placed as far toward the external border of the deep ring as is consistent with the integrity of the cord. It is important in placing this row of sutures that the stretched transversalis fascia be drawn well up in order to make it normally tense.

The deepest row of sutures having been completed the cord is dropped back and the aponeurosis of the external oblique united over it also by means of Kangaroo tendon. Either interrupted or continuous sutures can be used, being careful to invert the cut edges of the aponeurosis and make as taut as practicable without undue tension. Finally the skin wound is closed with interrupted sutures of silkworm-gut and a sterilized dressing applied, binding it on by means of a spica bandage. The bowels are moved on the second or third day, the dressings changed and skin sutures removed on the eighth or ninth day. The patient is kept in bed for three weeks. He is then allowed to go about, is warned against heavy lifting for several weeks longer and discharged with no truss or other apparatus to harass him.

This is about the method I have adopted in several cases and the results have been so gratifying that I do not hesitate to advise any patient with hernia

which causes him the least inconvenience, to resort to the operation. Great aseptic care must be used to guard against accidents. With such care I see no reason why the operation for the cure of inguinal hernia should not be practically free from danger and the percentage of relapses be almost *nil*.

GENERAL AND SPECIAL TREATMENT OF TUBERCULOSIS.

Read before the Dodge County, Wisconsin, Medical Society,
at Waupun, Wis.

W. E. OWEN, M.D.
FOX LAKE, WISCONSIN.

It is a source of pleasure to state in the words of an authority, Solis Cohen, that tuberculosis of the lungs is a curable disease. This authority, however, believes that the statement must be considerably modified with reference to the outcome of every case. We all realize from painful experience how utterly inefficient were our past resources in the arrest of these cases. There is no disease within the realm of medicine that gives the physician more prolonged and painful anxiety, because, in the first place, it is a pathologic process, generally occupying a lengthened period of time, whether in the direction of recovery or death; and in the second place, because we can not weigh in the balance the amount of potential energy possessed by the victim and the degree of vitality of the invading bacilli. We are thus surrounded by a cloud of uncertainty.

It may be well to generalize the situation by the statement that tuberculosis is primarily a local manifestation of a degenerative process, which may be limited to a few cells, or lobules of the lungs, or diffused, so to speak, throughout the economy, the characteristic tubercular process being due to some form of lesion whereby the active principle (the bacilli) gains a foothold through that gateway or entrance.

Degeneration of cells is produced by prolonged disregard of natural laws by predecessors, or promoted in the direction of depression, privation or excess. Anything either within or without the economy that is calculated to reduce the physiologic resistance of individual cells prepares the way for this dreaded enemy. We may also state the opposite, that everything within or without the economy calculated to maintain the standard of physiologic resistance are ideal conditions to ward off danger. With normal resistance of individual cells the microbes will come and go harmlessly. After the invasion of the tissues by the bacilli the struggle for existence continues, it being then a case of the survival of the fittest.

I have been deeply impressed of late by the suggestion, that we should examine the lungs of our patients more thoroughly and more frequently, especially those who have chronic dyspeptic symptoms and subject, by least exposure, to catching cold. When there is a persistent yellowish deposit on the tongue, after excluding malaria and rheumatism, we should suspect incipient tuberculosis; particularly when there is the least evidence of a predisposition in the family history. These symptoms, associated with indications of parenchymous change, constitute the so-called pre-phthisical state. It may be defined as a disposition of individual parent cells to produce a progeny of lowered vitality, brought about by conditions entirely outside of the cells; conditions which

produce mal-nutrition of cells. We shall not err very much by saying that in most of these cases the great battle for the supremacy between cell and bacillus has already commenced.

It is evident that to overcome this morbid state of mal-nutrition, our efforts should be directed towards making the environment as physiologic as possible. Our hope of relieving suffering humanity rests upon this principle generally speaking.

Nature has endowed all cells with wonderful recuperative forces, and providing that the parent curse of many generations does not rest upon any biologic cell, nor the surroundings be unfavorable, all living protoplasm by inherent forces will evolve from a lower to a higher state of physiologic vigor. I would suggest that these cases be treated, in all detail, as tubercular, even in the absence of any positive local symptoms. The treatment that promises any degree of satisfaction must be general. We must resort to all measures to improve nutrition, to bring the economy into harmony with its surroundings. We can not call to our aid any one specific, and I doubt if we ever shall; for independent of the invasion of bacilli are the degenerate cells. I feel, however, enthusiastic over the possibilities within reach of all. Our hope of a successful issue rests not upon directly fighting bacilli; but upon fighting degeneration of individual cells; upon increasing potential energy, modifying their surroundings, bringing the cells into harmony and equilibrium with environment. If we succeed in our efforts we may venture to disregard the bacilli, for we shall have succeeded in changing a favorable to an exceedingly unfavorable soil for their development.

A very essential beginning with these cases consists in ridding our patients of all disobedience and anxiety by laying the whole matter intelligently before them. In no other manner can we successfully protect the well and gain the patients harmonious co-operation. Inspire them with confidence and hope. Impress upon them the fact that by prolonged obedience to natural laws, rests their future welfare.

Cheerful surroundings are an essential factor to a successful issue; they aid nutrition reflexly through the mind. Prompt and thorough elimination of the products of normal and morbid tissue metabolism must be maintained. All the emunctories must be kept actively at work.

We will first take up the skin. By warm baths we increase its eliminative function; the superficial capillaries are filled and the lymphatic circulation stimulated so that subsequent inunctions of cod liver oil will be beneficial for nutrition and protect from cold. By cold bathing we stimulate the nervous system, and also train the economy to adapt itself to sudden changes of temperature without producing morbid reactions. Frictions after the cold bath will stimulate the capillary and lymphatic circulation.

The urinary secretion should be under constant observation, particularly its specific gravity. The specific gravity is usually increased. It is an indication for the administration of more fluids. A patient may take with advantage artificial lithia water or sterilized soft water, or better still, distilled water.

Of the alimentary organs, the liver demands the closest attention. Its influence for good or bad results is very great. It is called the graveyard for

blood cells. When there is a hard fight within the economy we have reasonable evidence that many phagocytes are killed in the encounter. The cells break down in the liver, and thereby increase the specific gravity of the bile. The demands upon the liver are frequently beyond its capacity for work. These cells, however, must be removed or the products of their disintegration will cause auto-infection.

These products, leaking, as it were, into the blood, make a very unphysiologic environment for the living phagocytes. Occasional minute doses of calomel, or preferable, as indicated biniodid of mercury, should be administered to reduce the pressure in the bile ducts. Free use of hot water will reduce the specific gravity of the bile. It may be well to stimulate the parenchyma by the usual remedies. A liver that has a normal capillary and biliary circulation will not let poisonous alkaloids leak (percolate) into the blood. Any abnormality in this direction causes passive pressure in the stomach and bowels that will retard digestion and assimilation. We must guard against prolonged retention of intestinal contents. Careful attention to the alimentary canal and its tributaries will result in greater capacity to digest food and prepare it for oxidation and assimilation. We all realize that the demand of the economy for abundant nourishment is very great in all these cases. Occasional flushing of the colon with sterilized water is worthy of attention. We must endeavor to keep up a vigorous circulation by vaso-motor tonics, systematic exercise, and massage.

Special attention should be given the nasal cavities; all obstruction to free admittance of air must be removed. They must also be kept scrupulously clean. We now come to the most important of our consideration of the treatment of tuberculosis of the lungs. It is not what shall we do with the bacilli, for this is a secondary matter, but the all important and vital question of how shall we maintain, restore or increase the capacity of the lungs? No part of the treatment has been more unsatisfactory in the past, and indeed, no part more disregarded. It is a fact that the largest majority of people with acquired tuberculosis of the lungs have not learned one of the greatest lessons in life, that of physiologic breathing.

Collapsed vesicles, hyperemia and lymph stagnation are nature's punishment for a disregard of her endowments. The decree of nature is, that a neglected organ will atrophy and degenerate.

It is an easy matter for plugs of mucus to settle in the vicinity of collapsed vesicles and there decompose. These mucous masses under normal conditions are expectorated. Wherever we have decomposing organic material there we shall find a plentiful supply of micro-organisms. It is a practical question to ask, how shall we open up these vesicles and relieve the hyperemia and lymph stagnation? It is a source of great pleasure to bring to your attention an apparatus, or instrument, called by the manufacturer, a pneumatic dilator, the principles of which are based upon the most sound philosophy.

Dr. Hawley describes it as an apparatus for preparing and administering nebulous medication by a process of forced dilatation, the basis of which is the discovery that the lips will act as a safety valve and that, into any tube, cavity or valve or air cell into which air can be forced by high pressure, the nebulous medicament prepared by this apparatus, can be forced with absolute safety, thereby enabling the

physician to use agents that are capable of preventing or controlling disease.

This discovery makes an important epoch in practical medicine. We should all grasp these principles with ecstasy for they tear open the thick clouds of despair that surrounded the wretched victims of this disease. I extend to it my fondest hopes for success, as it is destined to save many lives, of those otherwise doomed to an untimely grave. The practicability of the apparatus and process is self-evident. The principle is sound logic and not theoretical uncertainty. A full and elaborate illustrated description of the apparatus and process by Hawley has been published in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

But I have brought the apparatus here for your inspection, it will speak more eloquently for itself than any words of praise from me. As a prophylactic measure it is invaluable. One in health has but to experience the feeling of well-being by a single dilatation in order to appreciate its capabilities. There is absolutely no danger of rupturing either vesicles or tympanum, as the pressure is uniform, the lips giving perfect protection. By it the cardio-vascular and the pulmonary capacities are greatly increased, and to use the words of Solis Cohen, "resulting in increased function, increased elimination of waste products of function; with increased buoyancy of spirits which is no mean factor in treatment; in a word, heightened vitality."

That the capillaries throughout the body are wonderfully influenced is evident from the fact that the cold hands and feet become warmer. Williams also believes that dilatation of the alveoli in the neighborhood of the various lesions produces an important localizing effect and thus tends to prevent the spread of tuberculosis by secondary infection, from a caseous center or from a secreting cavity with inflamed walls, while the emptying of the vessels and of the capillaries of the region through alveolar dilatation leads to the absorption of caseous and cretaceous tubercular deposit. There is no more ideal treatment to prevent hemorrhage or control it after its occurrence, as it relieves the engorged vessels and removes congestion.

The mechanical principle of forced dilatation with air itself, you clearly see is invaluable; with these dilators, however, we can force into the lungs, the finest medical nebula imaginable. Ordinary inhalers for medicated air may be discarded, as we can not reasonably expect the medicament to get past the reserve air left after the most extreme expiration. They are regulated by the patient's will and consequently not satisfactory. By forced dilatation with nebulous medicament we overcome obstructions which offer an impassable barrier to ordinary inhalations. We can easily imagine the rapid diffusion of fine medicated nebula with the reserve air; and thereby attenuating, at least, the micro-organisms. We will demonstrate the explosive effect desired in order to remove the decomposing pulp of mucus. One bottle contains medicament for cough and all manner of bronchial irritation. The other contains the local specific for these cases—free iodine and chlorid of gold with menthol enough to mask the taste of the iodine. We can hardly realize the extent of the absorbing surface of the bronchi.

In addition to local effect, we also get systematic effects from absorption. For enlarged lymphatic

glands and lymph stagnation, the iodides are held in high esteem by general consent.

Above all else, however, we must endeavor to get as much pure air as possible into all these cases, as normal oxygen is the best excitant of the recuperative forces latent in all cells.

I have thought it waste of time to enter into consideration of the numerous remedies as we are all very familiar with their merits.

SOME REMARKS ON TEST MEALS.

Read by title in the Section on Practice of Medicine at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY HENRY SALZER, M.D.

CLINICAL PROFESSOR OF DISEASES OF THE STOMACH, BALTIMORE MEDICAL COLLEGE.
BALTIMORE, MD.

Test meals are given for the purpose of testing the digestive and motor power of the stomach, and thus judging of the condition of the mucous membrane and its glandular elements, as well as of its muscular action and its size, for an enlarged, or rather dilated, stomach depends chiefly upon these conditions.

The test meal now almost universally employed is Ewald's test breakfast, consisting of 30 to 50 grams of bread and 300 c.c. of warm water, or tea without sugar or milk.

One hour after this meal a soft, elastic tube is introduced into the stomach, and the entire contents of the stomach brought up, either by attaching an aspirator apparatus to the tube, or by pressing with the hand at the epigastrium, and encouraging the patient to assist this pressure by contraction of the abdominal muscles as it is done for defecation.

Other test meals have been suggested:

Leube-Riegel's consists of 300 c.c. of soup, 60 to 120 grams of meat and 50 grams of bread with 250 c.c. of water, and either the contents are aspirated or pressed out four hours later, when we expect the height of digestion, as we do one hour after the bread and water meal is taken, when it ought to be entirely empty, if both digestive and motor power are good.

Klenipere advises milk and bread, and two hours later, aspiration. The same time is recommended after the test meal of Germain See, which consists of 60 grams of scraped meat and 30 to 50 grams of bread.

Jaworsky's test meal is very complicated and requires a complete cleansing of the stomach by lavage, a meal of the whites of one or two boiled eggs and 100 c.c. of water, and aspiration every quarter hour for one and one-fourth hours, when the aspirated water becomes clear and acidulated and possesses digestive properties.

Boas advises as a test supper for atony a light meal late at night and lavage next morning, when the normal stomach is empty, while the atonic is not.

It is admitted that every one of these tests is useful, and that every investigator may reach good results with the method he prefers. The food obtained is in a state of advanced digestion, and permits the corresponding conclusions by inspection of the whole contents, by examination of the residue of the filter, and by chemical examination of the filtrate, which represents a true stomach juice at the height of action.

The Ewald breakfast gives these factors as well as the others; its use is very simple, and the masses we have to deal with are very clean and easily distinguished. Yet the disadvantage connected with this,

as well as with other test meals heretofore used, is the necessity of obtaining the entire contents of the stomach before one can judge if the muscular functions are normal. In health the entire residue after one hour should not exceed 20 to 50 c.c.

A further disadvantage of Ewald's test meal is, that it demonstrates the functions of the stomach in regard to only a very limited amount of work. For instance, Honigmann as well as myself, have found that with a more complicated test meal, *i. e.*, Leube's, the results with the same person showed marked differences. No impaired condition was found with the Ewald test meal, yet when a Leube test meal was used, the result was strikingly different.

Ewald and Boas advise in doubtful cases, the control test with a Leube-Riegel meal. These two factors, the necessity of a controlling test meal, and especially the importance of gaining by aspiration or pressure the entire contents of the stomach, is a great annoyance in private practice. It is very often the case that the patient is available only for a limited time and that repeated sittings can not be had to accustom him to the use of the tube; furthermore, by expression or aspiration parts of the mucosa are easily drawn or forced into the fenestræ or eyes of the tube, especially with patients not used to the manipulation, a factor which will be very unpleasant where peptic ulcer may exist, and where you may be especially anxious to gain an idea of an existing hyperchlorhydrie or at least hyperacidity. This objection can be made equally against the Einhorn bucket, which is very apt to bring up pieces of the mucosa, and is certainly not swallowed and removed more easily than a very soft, thin, elastic tube.

The following simple modification of the present test meals does away completely with all these inconveniences, and has been employed by me exclusively for the past three years to my greatest satisfaction.

I make the patient take early in the morning 30 to 50 grams of cold roast, free from all fatty and skinny parts and cut into small pieces one-eighth of an inch wide and about half an inch long; further 250 c.c. of warm milk, or milk and water, and 30 to 50 grams well-toasted wheat bread (dark-brown toast) or Zwieback. Four hours after this meal, 30 to 50 grams of stale wheat bread without crust or toasted particles, and 300 c.c. of warm water, or tea without sugar or milk. One hour later I introduce a thin, soft, rubber tube with two eyes near the lower end; this tube is inserted to the depth of from 50 to 60 cm. to reach the bottom of the stomach. In the case of tall persons, and of those in whom a splashing sound may be detected below the navel I prefer to insert it 60 cm. The tube is allowed to remain a few seconds, until some retching takes place, when it is slowly and carefully withdrawn, and in the case of great distress even without waiting for any contents of the stomach to appear at the upper end; if without any effort some flows out and a larger quantity can be obtained, so much the better. As soon as the stomach end of the tube leaves the mouth it is held upward and over a porcelain dish; by blowing gently into the upper end a sufficient quantity of the stomach contents (generally from 3 to 6 c.c.) is obtained to enable one to make all required tests. You see at a glance whether residues of the first meal are present or not. If there is only a milky, chyme-like addition to the bread and water, and no undigested casein, meat or toast, you know that the *motor* but not the

digestive function is more or less impaired. In health there should be nothing but what appears after a regular Ewald test meal. If casein and meat are undigested and the latter even apparently hardened, you know that there is sub- or anacidity and impaired albuminous digestion; if there are mostly pieces of toast, you have hyperacidity and impaired starchy digestion. The small quantity of stomach contents gained, shows before filtration every other abnormal addition, such as blood, surplus of mucus, bile, etc.

You can use red and blue litmus paper, Congo paper, and the Dimethylamidoazobenzol test. You can then gain enough filtrate to determine the degree of acidity, and to try the Uffelmann carbolic acid and chlorid of iron test for lactic acid, the phloroglucinvanillin test for even an approximative, quantitative muriatic acid, the biuret reaction for a peptone and propeptone test, the iodine test to prove the absence or presence of starch and erythroextrin, and a few drops for a rennet, or rennet zymogen test, and even a few drops to pour on a small piece of the white of an egg (hard boiled), or fibrin, for the pepsin test. You can do all that is generally done after a regular test meal, and have a perfect picture of the previous, more complicated digestion as well, especially for the estimation of the muscular power.

I have repeatedly convinced myself with others, as well as with my own stomach, that the tube always brings up portions of the first meal if any are still present in the stomach.

In introducing the tube a second time, pressing out every trace of the stomach contents, and using lavage until clear water appeared, I could always convince myself that the small quantity contained in the tube was a true representative of the entire contents of the stomach at the time. Nothing else could be expected, for we know from Beaumont's experiments with his Canadian, that those food particles which are not in proper condition to pass through the elective pylorus, either in consequence of chemical or other abnormalities, are thrown back into the stomach, even up to the cardia.

This fact is quite in accordance with the daily experience of eructations of food particles, which, indigestible pro-tempore, often show the taste of an article taken with a former and not the latest meal.

It is easily understood that the first meal will permit different modifications, and may, for instance, consist of rice, soft-boiled eggs, meat and milk or water; provided that it consists of articles of food which in health will disappear within a given time, and which will at the same time represent the albuminous, starchy and fatty types of food, in a way that the particles which remain undigested will show a conspicuous difference from the second meal, and not be large enough to obstruct the eyes of the tube.

It is clearly demonstrated that an amount of material fills the stomach tube when the latter reaches the fundus, which is sufficient for all clinical purposes, especially for the demonstration of the motor, as well as of the digestive faculties of the stomach, and that by this method these results are reached in a way the least troublesome and dangerous for the patient, and most convenient for the examiner, whether he makes his investigations from a physiologic or pathologic standpoint.

I can not close these remarks on test meals without alluding to a very important modification, which is

the result of the untiring efforts of Boas to gain positive diagnostic means, in cases where cancer must be suspected, but no tumor can be palpated.

He advises lavage in the morning, until the water becomes perfectly clear without any reaction whatever, then a test breakfast of a soup prepared of one tablespoonful of flour free from every trace of lactic acid and not apt to form it. He designates a special kind of oatmeal (Hafermehl) for this purpose. The amount of water to be used in preparing the soup he gives at 500 c.c.; after one-half hour (the average time in his experiments) the contents of the stomach are aspirated and examined. With these precautions, and only then, he found lactic acid present (with but very few exceptions) only in cases of malignant disease.

SPASMODIC ASTHMA CAUSED BY AORTIC ANEURISM.

BY GEORGE TULLY VAUGHAN, M.D.

PASSED ASSISTANT U. S. MARINE HOSPITAL SERVICE.

It seems to me that a form of dyspnea, which closely resembles spasmodic asthma and from which it seems at times impossible to differentiate it, as a symptom in aortic aneurism, is important enough to deserve especial notice. In the three cases I am about to report it was a prominent and distressing symptom while other symptoms of aneurism were rather obscure. Asthma from aneurism is no doubt caused by pressure on the pneumogastric nerve and is not always continuous as might be supposed, for in one of my cases the patient had only three attacks in all and these occurred at irregular intervals during the last two months of his life. In the other cases this symptom was continuous but with marked remissions.

In obstinate and persistent cases of asthma in elderly persons, aneurism should always be born in mind as a possible cause, for in the absence of bruit, impulse, swelling, or circulatory disturbances it is not always easy to make a correct diagnosis. The pressure symptoms which cause changes in the pupil, paralysis of a vocal cord or unilateral sweating are not sufficient, as any other mediastinal tumor may produce the same effects.

"Tracheal tugging," first described by Surgeon-Major Porter of the British Army is a symptom of great value. It is brought out by taking hold of the cricoid cartilage when the patient is sitting with the neck relaxed, and putting the trachea slightly on the stretch. If there is aneurism of the arch, a distinct tugging of the trachea is felt with each pulsation of the heart.

Case 1.—J. F. C., aged 60 years, native of Maine, was admitted to the Marine Hospital at Boston, Mass., June 14, 1888, with this history: Was first taken a year before with pain in left side of the chest from breast to back and in the left shoulder. Slight cough and once expectoration of a little red blood. Felt well after this until winter, when, after "taking cold," the pain and cough returned, there was nausea, unpleasant symptoms after eating, and loss of flesh. In appearance the patient was thin, with unhealthy color of skin, suggesting malignant cachexia.

Respiration in the left lung was weaker than in the right, but the heart seemed normal and no bruit nor tumor could be detected. There was little change, patient expectorated blood two or three times, until about two months before death when he was suddenly taken with extreme dyspnea with all the signs of constriction of the bronchial tubes on both sides, rales, wheezing and orthopnea, lasting an hour or two when it was in a great measure relieved by morphia.

In a day or two he was about as usual until the next attack, having in all three severe attacks and dying in the third.

Necropsy. Left lung weighed 170 grams, was small, atrophied and the seat of a low grade of inflammation; its pleural cavity was obliterated by adhesion. Right lung weighed 250 grams, congested, some adhesions of pleural surfaces. Heart weighed 310 grams, valves normal. The sinuses of Valsalva were incrustated with calcareous nodules, the aorta dilated at its origin to double the normal size and gradually increased to the beginning of the transverse portion of the arch where the expansion was much greater and formed the beginning of a large fusiform aneurism which extended from this point to the lower border of the seventh dorsal vertebra, including the left sides of the bodies of five vertebrae with the heads and necks of the corresponding ribs. The posterior wall of the sac was formed by the exposed bone from the third to the seventh vertebra inclusive. The bodies of all were more or less eroded and the heads and necks of the fourth and fifth ribs had been completely absorbed. The spinal canal was intact. The walls of the sac were thick and firm with deposits of organized clots in places interspersed with plaques of calcareous material. The edges were firmly adherent to the vertebrae and there was no rupture. Capacity of the sac about fifteen hundred cubic centimeters, nearly filled with loose antemortem clots. There was evident pressure on the left vagus nerve.

Case 2. G. C., aged 57 years, native of the United States, was admitted to the marine ward of the German Hospital, Philadelphia, July 15, 1895; died July 19, four days later. Patient stated that he had been suffering from asthma (according to his physicians) for nine months constantly, though at times he was better. On examination there was orthopnea, prolonged expiration, wheezing, râles all over chest, respiration weaker in right lung, and occasional cough. Circulation and heart sounds apparently normal, though the examination was not satisfactory owing to the râles and dyspnea. Aneurism was diagnosed as probable, chiefly on account of the persistent dyspnea and the feeble respiration in the right lung. Tracheal tugging was not sought. Of various remedies tried morphia afforded most relief, but the dyspnea continued and the patient died from exhaustion.

Necropsy. Heart hypertrophied, especially the left ventricle; atheroma of the base of the aortic valve though the valves were competent. The aorta was dilated and from its arch, anteriorly, between the origin of the arteria innominata and left common carotid, arose a saccular aneurism, capacity about four hundred cubic centimeters, filled with a hard, laminated, grayish clot. The edges of the sac were attached in front to the posterior surface of the manubrium between the first and second ribs, the bone being eaten through on the right side, but forming scarcely a perceptible bulge in front. The lumen of the aortic arch seemed little, if at all, encroached on, the tumor pressing especially on the arteria innominata, the right bronchus and right pneumogastric nerve. There was no rupture of the sac and death must have been caused by pressure on the vagus nerve.

Case 3 has not yet come to a necropsy. J. B., aged 48 years, native of Maine, a tall, 6 foot 3 inch, powerful-looking man, was admitted to the marine ward of the German Hospital, Philadelphia, Sept. 18, 1895. History: Family history good; admits gonorrhea, denies syphilis; had "rheumatism" in 1896, but no fever nor swelling of the joints; has had slight cough with expectoration of mucus for three years. For the past eight months says he has suffered from "asthma" which is worse by spells and generally worse on lying down. Three months ago he was taken with pain in the right shoulder, right side of the neck and left knee. Examination: Breathing high pitched over both lungs. Numerous râles, coarse and fine, over both lungs, especially at end of inspiration. A diastolic murmur was heard over the upper part of the sternum, but no thrill nor pulsation could be felt and there was no pain nor swelling. Hard, dry, high pitched, metallic cough at intervals of half hour or hour, night and day. No inequality of the pupils, but he states that the right side of his face sweats more than the left. A distinct though slight tracheal tugging is perceptible with each heart pulsation.

The diagnosis was aneurism of the arch of the aorta. October 17, patient asked attention to a swelling behind his left knee which he first noticed three months ago. There was some pain at first but lately he has felt only weakness in the leg.

An aneurism as large as a pigeon's egg was detected in the popliteal space. By an oversight his leg had not been examined before.

October 26, pulsation can now be felt over the right sterno-clavicular articulation and there is unmistakable bulging on this side, thus removing all doubt, if there were any left as to the correctness of the diagnosis.

The patient was put on the Valsalva-Tufuell treatment but could not stand it and was allowed to get up. The operation of ligation of the subclavian and carotid arteries was explained to him but did not meet his approval and he was discharged at his own request. Nov. 4, 1895, not improved.

PURULENT OPHTHALMIA.

Prepared for the Mitchell District Medical Society of Indiana.
Dec. 26, 1895.

BY DUDLEY S. REYNOLDS, A.M., M.D.,

PROFESSOR OF OPHTHALMOLOGY, OTOTOLOGY AND MEDICAL JURISPRUDENCE
IN THE HOSPITAL COLLEGE OF MEDICINE; SURGEON TO THE EYE
AND EAR DEPARTMENT OF THE LOUISVILLE CITY HOSPITAL, ETC.
LOUISVILLE, KY.

Purulent conjunctivitis should have a degree of significance to the physician according to the character of the infection and the age of the patient. While there are many varying degrees of intensity, for clinical purposes, it is best to recognize but two causes; the gonorrheal and the endemic.

The gonorrheal is most malignant and intractable; it seldom occurs in both eyes simultaneously. It is most common in adults, and is the result of contagion. The endemic is equally contagious and differs in its clinical features from the gonorrheal type in degree of severity and extent of invasion. In gonorrheal inflammation, the cocci not only attack the mucous corpuscles and surface epithelium, but penetrate quickly into the mucous follicles, which become greatly distended, causing such interruption in the circulation of the blood in the capillary coils surrounding the follicles that great edema is quickly set up, producing a degree of swelling of the ocular conjunctiva often quite sufficient to very nearly overlap the entire cornea, giving to its vertex a decidedly umbilicated appearance.

These phenomena are never seen in the endemic form, which depends upon the presence of one or the other of two varieties of staphylococci. The disease in its earliest stages, presents a golden yellow colored pus, or a cream colored stringy muco-pus. In the gonorrheal infection there are always extensive abrasions of the surface in the lining of the lids. In the endemic type this never occurs, and while there are in reality two distinct forms of staphylococci which produce purulent conjunctivitis, one of them stringy, the other golden yellow, there is little difference in degree of severity and in the clinical course of the inflammation. In the new-born, the endemic is the most common type of purulent inflammation, and it is vastly more dangerous to the cornea, than in adults. It is extremely doubtful if any case of gonorrheal conjunctivitis ever resulted from maternal infection in the course of natural delivery. In the first place, as is well known, the skin of the fetus is everywhere covered with the vernix caseosa, the eyes being closed. After the birth of the child, when the eyes are opened, the lash lifts away all external matter, and its arrangement along the free borders of the lids is such as to constitute a practically impassable barrier for any matter that might be lodged upon the skin, even if it be of a fluid nature. When the nurse undertakes the removal of the cheesy coating from the skin, the eyes are frequently inoculated with whatever matter may be on the rag or sponge. Staphylococci are nearly constantly present about the finger nails and sponges handled by untidy persons; and simple muco purulent vaginitis, with which the mother or nurse may be suffering, constitutes a vastly more common source of inoculating

the eyes of the infant through the carelessness or ignorance of the nurse than any possible gonorrheal state of the maternal passages.

Did you ever think for a moment, those of you who have seen gonorrhea in the female, how it almost invariably provokes miscarriage, or abortion; and, how, if it exists prior to pregnancy, it makes that condition impossible during the existence of the infectious inflammation? It is extremely rare that a pregnant woman, in the advanced stages of gestation, contracts gonorrhea, and yet this would appear to be the only class of cases in which gonorrheal ophthalmia neonati might be possible from maternal infection. Credé concluded that purulent ophthalmia neonatorum might always be prevented by having the new-born subjected to an instillation of a 2 per cent. solution of nitrate of silver into each eye. In the attempt to carry out this suggestion, the eyes of many are infected which might otherwise escape. Under strictly antiseptic rules, Credé's method might possess some virtue, but with the always to be desired and ordinarily aseptic conditions, all interference with the eyes is unnecessary, and even meddling. In the obstetric wards of a general hospital, the most abundant evidence of the faults of this system, owing it may be to the imperfect methods of those in charge, have been clearly apparent. Since the attempt to employ Credé's method, but few children born in that hospital have escaped purulent ophthalmia, a disease comparatively unknown there prior to the attempt to introduce this system. The best protection for the eyes of the new-born in public institutes where asepsis is easily maintained should be complete non-interference. Where sepsis may reasonably be feared, the nurse who takes charge of the infant should be an entirely different person from that one who takes charge of the mother. The only proper course to pursue, in such dangerous conditions, is to insure complete isolation until after all those preliminary stages relating to the cleansing and dressing of the infant have been completed. If the nurse in charge of the infected mother is permitted to touch the eye of the infant, experience shows that infection of the eyes will be almost inevitable. Neither Credé's solution, nor any other chemie agent may prevent disaster. I have known an interne within ten minutes after delivery, seize the infant and, separating its eyelids with his fingers, order the silver solution instilled by the nurse; next day purulent ophthalmia appeared. The mother was not then infected, but had two days later well characterized puerperal fever. The interne had examined an infected woman before delivery. In other cases, the child's face and neck are washed and wiped off with a rag, which is subsequently folded upon the nurses finger and employed to remove adhering particles of vernix from the vicinity of the inner canthus, the same process being repeated at subsequent ablutions. In due time they are inflamed, and the maternal passages are accused. I am convinced that, if physicians and nurses generally, as is the custom in private practice, could be taught the danger of attempting to touch the eyes, much more good would be accomplished than it would be possible to secure by the use of any kind of chemie antiseptic agent. The aseptic rule in this field is just as precious as in any department of surgery, and the attainment of antiseptic principles just as difficult and uncertain.

As to the treatment of the varying forms and

stages of purulent conjunctivitis, it seems to me necessary that something should be said. It has been too long the custom to seek chemie antidotes for specific types of inflammation, and to regard all the purulent forms of conjunctivitis as the old-fashioned doctors did similar processes in the male urethra. It was long the custom to treat such cases with active caustic applications, and powerful astringents. Experience must have convinced any ordinary observer that these methods of practice are not only dangerous, but rarely curative. The most successful treatment of gonorrhea in the male is through the medium of the circulation, and not by local injections; and where these are practiced in the advanced stages, they are of a far milder character than were formerly employed. The same rule applies to the treatment of gonorrheal inflammation in all mucous membranes, whether it be the conjunctiva, the vagina, or the urethra. The object being to keep accumulating matters constantly washed away, and to so sterilize the surfaces as to retard the activity of the growth of the ferment, and, in this way, the earlier stages of the disease are held in such control as to prevent deep seated invasion, and consequent necrosis of the cornea. In the more advanced stages of the infection such stimulating agents as do not impair the vitality of the young epithelial cells may be employed. Astringents are, however, never to be used here. In the first stages of gonorrheal infection, bichlorid of mercury in the proportion of one-sixteenth of a grain to the ounce of water containing ten grains of chlorid of sodium, may be freely used with the irrigator every ten minutes, until there is manifest abatement of the discharge, when the interval may be gradually prolonged until finally, when no more pus is formed, it may be discontinued altogether. In the virulent gonorrheal types of inflammation, Jeanel's emulsion of copaiba may be instilled every four hours with great advantage. To illustrate this treatment, permit me to recite the case of C. L., aged 19: He came from the country with gonorrheal ophthalmia of four days standing; the cornea in the right eye had already sloughed, leaving the iris exposed in the central portion; a small part of the superior pupillary margin being still protected by an overlapping edge of the posterior elastic layer of the cornea, led me to employ sulphate of atropin solution in the attempt to dilate and thereby retract this part of the iris from the vicinity of the perforation. The cornea throughout all the remaining portion was so infiltrated and opaque as to make it impossible to see the iris. In the left eye, the cornea presented a gray, cream color, the surface epithelium being thoroughly infiltrated and abraded in small areas. The urethral discharge was very profuse, as well as the discharge of pus from the conjunctiva. I gave him five minims of balsam copaiba, in a capsule, every three hours, and two drachms of Rochelle salts, in one pint of water every morning. He was directed to have his eyes irrigated every ten minutes with the following:

R. Bichlorid of mercury	gr. viii	48
Chlorid of sodium	3 iii	90
Distilled water	cong. i	3840
Sulphate of atropin	gr. ii	12

He used, as a collyrium, every four hours, the following:

R. Jeanel's emulsion of copaiba	3 ii	60
Distilled water	5 vi	24

Two weeks after admission to the hospital he returned home, able to read with the left eye, and to count fingers across the room with the right. This result could not have been attained by any very widely different plan of treatment.

ILEUS.

BY JOHN B. MURPHY, A.M., M.D.,

CHICAGO.

(Concluded from page 22.)

Mechanic ileus.—In the diagnosis of internal strangulation, no matter from what cause, we have exactly the same symptoms as in strangulated hernia, except the physical signs are different. The symptoms of internal strangulation are as follows: Pain in the abdomen which comes on suddenly, gradually increasing in intensity for the first half hour, followed by nausea and vomiting, and inability to produce bowel movement. If the strangulation be severe, there is an increase in the frequency of the pulse (but as a rule in the early stage the pulse is not accelerated), *absence of temperature*, absence of tenderness. As the case advances, if the strangulated coil be large, it can be recognized through a moderately thin abdominal wall by its distension; the coil of the intestine leading to it may also be recognized by a circumscribed elevation of the abdominal wall. In twenty-four hours all of these symptoms will have increased in severity. The distention of the coil is greater, the abdomen is more tympanitic, sensitiveness at the seat of obstruction is now manifest, and the increased resistance of the occluded coil may be felt. If the coil be small, the increased resistance of the intestine on the proximal side of the occlusion may be felt and a circumscribed dullness be outlined. This varies with position, depending upon the portion of the intestine involved in the strangulation, as shown in the von Zoege-Manteuffel plates. *Peristalsis is very greatly increased and is most pronounced in the neighborhood of the obstruction.* This increase in peristalsis continues until peritonitis sets in, when it entirely disappears. If the strangulation be sufficient to produce gangrene the depression will be more marked, but the local manifestations unchanged. *Opiates paralyze peristalsis for hours and therefore should never be given in acute intestinal lesions as they obscure the symptoms and signs of the pathologic process.*

The following cases are good illustrations of internal intestinal strangulation:

Mr. C., aged 37 years, robust, had always enjoyed excellent health. Six days before admission to the hospital was attacked with pain in the abdomen, moderately severe, followed by nausea, persistent vomiting, and inability to produce bowel movement. The symptoms continued notwithstanding intestinal irrigation and frequent doses of cathartics. When admitted the pulse was 100; temperature 99 degrees, and it had not exceeded that at any time since the onset. Expression good; abdomen very tympanitic, greatest distention being just above the umbilicus. Increased resistance in neighborhood of umbilicus; abdomen slightly sensitive. Diagnosis intestinal obstruction. Laparotomy. A loop of bowel was found twisted around a Littre diverticulum attached to the umbilicus, evidently congenital. The coil was distended, cyanotic, surface glistening but not gangrenous. There was no peritonitis. The diverticulum was ligated, excised and invaginated, the coil liberated; circulation became reestablished, and the abdomen closed. Time occupied in the operation twenty-five

minutes. The patient's pulse increased in rapidity, the vomiting subsided, the bowels moved freely, nevertheless, he died nine hours after the operation. Post-mortem showed no peritonitis: strangulated portion of the intestine congested but not perforated; mucous membrane ecchymotic; small veins thrombosed.

What was the cause of death? It was certainly not the strangulation, nor peritonitis, but auto-infection either from absorption of the decomposed proteids that began rapidly after the liberation of the obstruction, or an auto-infection through the thrombosed intestinal veins, more likely the former, as we have exactly the same results where the gangrenous intestine and infected veins have been resected.

Case of internal strangulation in a sub-peritoneal pocket at left internal inguinal opening;

Mr. C., age 22 years; printer. On the morning of October 25, when lifting a heavy case, "felt something give way" in the left inguinal region. The pain became so severe he was compelled to stop work and go to bed. Six hours after the onset vomiting began and continued at frequent intervals up to the time of operation. Impossibility to produce bowel movement. I saw him three days after the onset of symptoms. *Status presens:* Face sunken, eyes prominent, anxious, depressed expression; pulse 90, temperature 98.8 degrees; breathing somewhat labored. Abdomen tympanitic, most prominent in lower left portion; resonance irregular; sensitive over left inguinal ring; a slight induration could be felt above and to the left of the internal ring. The inguinal canal was free, the finger could be passed through it. Peristalsis was greatly increased; rectal examination negative. The patient located the difficulty in the left inguinal region.

Diagnosis: Internal mechanic ileus. Section; median incision; passed the hand down to left internal ring, found the coil bound fast at the ring. Exposed the parts and found a peritoneal pocket extending upward and to the left subperitoneal, *i. e.*, between the parietal peritoneum and the muscular fascia. Incised the constricting ring and opened pocket; bowel in good condition; not resected. Peritoneal sac removed and opening sutured. Abdomen closed. Rapid recovery.

Case of strangulated diaphragmatic hernia. Referred to me by Dr. Richard Haley:

J. H. M., age 31 years; single. Admitted to Mercy Hospital July 15, 1895. The patient, a well-developed, muscular brakeman in excellent physical condition, states that he has had repeated attacks of abdominal pain and vomiting with inability to produce bowel movement in the last six years, usually lasting from ten to twelve hours; had never had a severe injury. The pain was always located in left hypochondrium. Present attack began six days ago with the usual symptoms, slight pain in left hypochondrium; vomiting, not excessive, biliary in character; no passage from bowels of gas nor feces from that time. *Status presens:* Patient's expression good; pulse 86, temperature 98.7 degrees; breathing somewhat labored; abdomen very much distended. Borborygmus so marked that it could be heard in any part of the room; pain not severe; tenderness most marked in left hypochondrium, but nowhere excessive; auscultation revealed increased peristalsis, most marked in right hypochondrium, but present in all portions of abdomen; percussion elicited areas of dullness over lower half of abdomen, largest to right and below umbilicus; they were outlined with ink on the surface of the abdomen and changed position while being transferred to the hospital where he was re-examined. The transverse and ascending colon could be outlined by inspection and percussion. They were greatly distended. Section; median incision: small quantity of serum escaped. The sigmoid flexure found contracted and empty; followed it up to large bowel and the latter to splenic flexure, which could not be drawn into the field. Small intestine was very much distended with fluid feces. The colon ascendens and transverse enormously distended with gas, but contained no feces. The greater portion of the bowel had to be turned out to allow access to the obstructed splenic flexure of the colon. A careful examination showed the cause of the obstruction to be a strangulated diaphragmatic hernia; the opening was situated two inches from the ribs and about the junction of the posterior with the middle third of left leaflet; it was most difficult to reach. Traction failed to move the strangulated portion. With the greatest difficulty the tip of the finger was inserted under the edge of the ring, which was divided on the finger with scissors. The intestine was liberated and examined; the circulation was rapidly restored; no

resection necessary. The intestines were removed from the warm protections and returned by the "towel method" of reduction, which I have used on many similar occasions and found very effective. Abdomen closed. The sphincter ani was then paralyzed by over-stretching.

In the operation the patient had excessive and true fecal vomiting. This was accounted for by the obstruction being so far down in the large intestine. Patient's condition fair when the operation was completed. Had copious and frequent bowel movements three hours after operation. Soon showed severe symptoms of shock; pulse rapidly increased in frequency; in seventeen hours it had reach 142; temperature 105.2 degrees. Hippocratic face with marked excitement and anxious mental state. This condition continued until death, which occurred forty-three hours after operation. Post-mortem was not permitted.

Volvulus is a rare form of internal ileus. By volvulus we mean a twisting of the intestine upon itself for more than two-fifths of a circle; less than this does not produce obstruction. We have all the symptoms of ileus; the pain is mild; the vomiting is persistent; inability to produce bowel movement; absence of temperature. In the early stage the patient shows very little depression; pulse negative. As soon as the coil of the volvulus becomes distended, it can be recognized by its shape through a moderately thin abdominal wall; the local meteorismus; increased resistance local; great increase of peristalsis until peritonitis supervenes. The following case, referred to me by Dr. J. L. Piper, is typical:

Mr. S., aged 68. Nov. 10, 1893, was seized with pain in the abdomen shortly followed by vomiting, inability to produce bowel movement; slight tenderness; diagnosis by Dr. Piper, intestinal obstruction. I saw him thirty hours after the onset of symptoms; he then had but little pain; the vomiting was frequent and severe, the matters ejected yellow and offensive; pulse 72; temperature normal; abdomen distended, most prominent a little below and to the right of umbilicus; increased resistance at this point; tympanitic; excess of indican in urine. Patient removed to Presbyterian Hospital. Celiotomy. The hand was passed down to the right and the distended coil drawn into the opening. The distended intestine measured over two and a half inches in diameter; a coil of 12" was found twisted upon itself; when this was straightened a loud report was heard from the escape of gas; there was no gangrene nor peritonitis; intestine returned. Patient made an excellent recovery.

Frequent in the benign mechanical obstructions is cicatricial contraction of the intestine itself. In these cases the onset is gradual, so much so that the patient suffers from intestinal disturbance a long time before the final occlusion takes place. This occlusion frequently manifests itself as a seizure with pain, nausea, vomiting, no elevation of temperature,

no change in pulse, inability to produce bowel movement. Note following case:

Mrs. E. T. S., aged 53, referred to me by Dr. Jas. J. Fortier. The patient, three days previous, was suddenly attacked by pain in abdomen, persistent vomiting, inability to move bowels. These symptoms continued until time of operation. When patient entered Post-graduate Hospital she still complained of pain; slight tenderness. A hard tumor the size of a child's head could be felt just above the symphysis; abdomen tympanitic, slightly tender, greatest resistance on the left side of tumor; percussion note except over tumor resonant; pulse 96, temperature normal. Diagnosis, dermoid cyst; intestinal obstruction, probably from bands. The patient stated positively that the tumor was not present until the attack came on, but this was not credited. Laparotomy June 2, 1893. Median incision; dermoid removed; distended coil of intestine drawn out and with it a stricture, a cicatricial band completely occluding the bowel for one inch; resection of two inches of bowel and end-to-end approximation with button. Time for making resection five and a half minutes. Time for entire operation—removing dermoid, making resection, and complete closure of abdomen, nineteen minutes. No drainage. Convalescence uneventful; button voided on the tenth day. July, 1894, patient in excellent health.

Invagination (intussusception) occurs more frequently in children than in adults. The onset is sudden; the patient usually gives a piercing shriek from pain in the abdomen; depression produced is very great; the pulse increases rapidly in frequency; the vomiting is persistent; the eyes sunken; cold perspiration. These symptoms continue for about two hours, when they gradually diminish. The vomiting persists, but is less severe; after twenty-four hours blood may be detected in the stools. The following case was referred to me by Dr. F. S. Hartmann: Baby. B., aged 7 months, shortly after nursing gave a loud and piercing cry and began to vomit; cold perspiration and collapse. When seen by Dr. Hartmann a few hours later, pain was less severe; a distinct oblong tumor could be found in the right hypochondriac region just below the margin of the ribs; no bowel movement could be produced. The same afternoon the patient was removed to Cook County Hospital. Laparotomy ten hours after onset of symptoms. Tumor in right hypochondriac region was very distinct; median incision; tumor grasped with the fingers and found to be the cecum and colon into which the ileum was invaginated. Very friable adhesions had formed, but pressure upon the colon forced the ileum out without traction. Abdomen closed; perfect recovery; patient left hospital after seven days.

When the obstruction is due to a gall-stone or a foreign body in the intestine, the symptom of vomiting is very marked, the meteorismus is less and the depression less, as the foreign body is constantly changing its position and advances further in the intestinal canal.

The following case illustrates intestinal obstruction from enterolith:

Case 1.—J. McC., age 47; male; admitted to Cook County Hospital Dec. 1, 1895. Family history negative. Personal history: Uses intoxicants and tobacco to excess; had gonorrhea three times; denies syphilis; typhoid fever when a boy; about twenty years ago was seized with sudden severe pain in the epigastrium; he describes the pain as a cramp, says it

lasted but a few hours: since that time has had many similar attacks: present illness began five days ago: after a large bowel movement, was seized with severe, steady, aching pain in the epigastrium which confined him to bed: the following evening patient began to vomit a dark-colored material: shortly after the material ejected became offensive: the severe pain, vomiting and inability to produce bowel movement has continued up to the present.

Physical examination: Well nourished: conjunctiva slightly jaundiced: tongue dry and heavily coated: breath very offensive: face has a pinched expression: knees drawn up: abdomen distended: irregular elevations can be noticed on its surface: liver dullness normal: the peristaltic movement could be recognized through the abdominal wall: auscultation revealed stormy peristaltic action, most marked in the epigastrium and on the right side: no tenderness except to the left and a little above the umbilicus, where deep pressure produced pain. Pulse 90: temperature normal.

Diagnosis: Mechanic ileus without intestinal strangulation. Celiotomy Dec. 6, 1895. Assisted by Drs. Besley and Wood. Median incision: small intestine very much distended: a portion secured and held by assistant: splenic flexure of colon located: found contracted and empty: advanced along the transverse colon until near the median line, when a nodule was felt in the small intestine. The transverse colon was then dropped and the nodule in the small intestine drawn into the wound. The intestine above the nodule was about two inches in diameter, below the nodule five-eighths of an inch. It could readily be seen that the obstruction was produced by a large foreign body in the bowel. A parallel incision was made and a large enterolith extracted. Opening closed with a Czerny-Lembert suture. Abdominal wound closed with silk-worm gut: no drain.

The enterolith weighed 25 grams. It measured $4\frac{1}{2}$ cm. longest diameter by 2.75 cm. shortest. Its circumference was 12 cm. The center appeared to be made up of an old dry mass of plum pudding, to which other material had become adherent. It would be interesting to know whether this had been the cause of the attacks of pain which he had had for twenty years preceding the operation, and if it had been in the canal where it was lodged. We do know that the anastomosis button may remain in the bowel for months without producing manifestations of its presence. The differential diagnosis between strangulation ileus and obturation ileus in this case was based on the fact that the man had suffered for five days from obstruction and still was not collapsed nor severely depressed by it. The patient made an uninterrupted recovery.

We have in strangulated hernia the same symptoms as in internal strangulation, and in addition thereto we have a history of hernia, and the presence of an irreducible tumor. The peristalsis is increased and there is an absence of induration in the abdomen, except where peritonitis is present. When peritonitis is present there is a marked induration about the seat of obstruction and an absence of peristalsis in that region.

The following cases are illustrative:

Case 1. Mr. C., aged 58. Referred to me by Dr. T. A. Lilly. Gave a history of hernia of twelve years' standing. Twenty-four hours before he came under my observation the hernia was down, and at that time he received a kick in the scrotum. It was followed by pain: the patient continued his work as usual, but at night was unable to return the hernia as had been his custom. He remained in bed the next day, and sent for the doctor in the afternoon. An irreducible strangulated hernia was detected and the case referred to me. Patient's pulse 100: temperature 100.3 degrees: abdomen tympanitic, induration extending over an area of five inches from the inguinal canal: absence of peristalsis over that region. No effort made at reduction and patient would not consent to operation at that time: but the following day he was taken to hospital. Herniotomy performed. On opening the hernial sac there were found two perforations of the coil of intestine, evidently the result of the traumatism. The coil was surrounded by pus: circulation not strangulated. Abdomen opened, and suppuration was found to extend about six inches from the inguinal opening. Intestines matted together, a large pocket of pus in the neighborhood of the inguinal canal, and three or four feet of the intestine covered with a pyo fibrinous exudate. Peritoneum cleansed, pus carefully removed from surface of intestines, perforations sutured, coil returned, position of sutures kept at opening in the abdomen, the latter packed with gauze, glass drain inserted. Patient's condition was excellent for fifteen hours:

his bowels moved: he then began to sink rapidly, and died twenty hours after operation. Post-mortem not permitted.

Case 2.—Referred to me by Drs. Jennings and Berry. History of strangulated hernia. Three days previous the hernia came down and could not be reduced. The pain was more severe than at any previous time. The patient had made protracted efforts at its reduction, but did not succeed. A doctor was consulted and the hernia apparently reduced, but the pain, vomiting, and inability to produce bowel movement continued.

Examination three days after onset of symptoms showed the abdomen uniformly distended: absence of abdominal respiratory movement: induration circumscribed by an arc of five inches from the inguinal ring: peristalsis over that area absent: present on the other side of the abdomen: temperature 101 degrees. Diagnosis, strangulated hernia: perforative peritonitis. Operation. Sac opened, and found to contain a small knuckle of intestine not strangulated, feces and pus. An opening half an inch in length was found in the coil of intestine, not from gangrene, but cut apparently by pressure against the ring in the patient's efforts at reduction. Enlarged opening in abdomen. Peritonitis circumscribed, half a pint of pus in the iliac fossa, twenty inches of intestine covered with a fibropurulent exudate. Peritoneum cleansed, sac amputated, opening in bowel sutured (Czerny-Lembert), and retained near wound in the abdomen. Packed with iodoform gauze, glass and gauze drains. The following day the patient's condition

Fig. VIII

was fair and continued so until the third day, when singultus began. This persisted for four days, the patient vomiting once every six or eight hours. A bowel movement was produced on the second day and frequent passages kept up from that time. In ten days the gauze drain was removed, and the patient made a slow but perfect convalescence.

These two cases illustrate the characteristic signs of infective peritonitis following strangulated hernia; that is, beside the usual symptoms of obstruction there was elevation of temperature; absence of peristalsis near the position of obstruction, and induration. In neither of them was the coil of intestine gangrenous, and therefore not resected but sutured. It was fortunate for the patient in both cases that the hernia could not be completely reduced.

Strangulation of the omentum produces usually the same symptoms as an intestinal obstruction, and they continue for three or four days, depending upon the degree of strangulation. If it be sufficient to produce a necrosis they will continue until gangrene is complete. This may occur without producing a sup-

purative peritonitis, nor even an infection of the sac and absorption may take place. It is not uncommon, however, to have an incarcerated or strangulated omentum suppurate, and it should not be reduced. The same practice should govern its reduction, as the reduction of a strangulated intestinal hernia, that is, a hernia of more than thirty-six hours duration should never be reduced except by operation where the coil can be examined.

The following is an illustration of the importance of this principle in omental strangulation:

Mr. R., referred to me by Dr. W. W. Wetherla, and admitted to St. Joseph's Hospital. The patient stated that in alighting from his buggy forty-eight hours before, his hernia came down, as it had done repeatedly for fifteen years. He could not reduce it. The doctor was called thirty-six hours after the obstruction occurred and finding that the hernia could not be reduced, advised operation. Herniotomy was performed forty-eight hours after the onset of symptoms. The strangulated omentum was suppurating, and infiltrated with a fibropurulent exudate: fresh adhesions to sac evidently prevented

the reduction. Omentum amputated; stump returned, and Bassini operation resorted to for radical cure; sac removed, abdomen closed, complete primary union notwithstanding the presence in his perineum and scrotum of a number of old suppurating fistulae. I believe that the source of the infection was through the lymphatics from the perineum and scrotum. In this case, as in the two preceding ones, the hernia could not be reduced.

Another danger following reduction of hernia is that it may be reduced *en bloc*, or a small knuckle may be allowed to remain in the ring. In these cases the symptoms of obstruction do not subside after the reduction, and it should be the rule that in all cases of reduced hernia, where the symptom of vomiting continues for six hours after reduction, a laparotomy should be performed.

Mrs. K. Referred to me by Dr. Blank. Patient had a strangulated umbilical hernia of two days' duration when the doctor saw her. It was returned; the symptoms of vomitine continued, and the patient's abdomen became more and more distended. No bowel movement could be produced. The

vomit had the peculiar odor of decomposed intestinal contents, not fecal. The patient's countenance denoted great depression. I saw her five days after the initial symptoms: at which time the extremities were cold, a cold perspiration over the entire body: lips cyanotic: eyes staring and glassy, and the patient in the most profound collapse. Examination of umbilicus showed the opening free, but on passing the finger into the ring an indurated nodule could be felt on the right side. No operation. Patient died two hours later. Post-mortem showed small knuckle of strangulated gangrenous bowel in one of the pockets of the sac, so commonly found in umbilical hernia.

As an illustration of incomplete reduction, the following is a most instructive case, referred to me by Dr. John W. Hanna of Winfield, Iowa.

Patient admitted to St. Joseph's Hospital, December 30, 1894. Six days previous, when he alighted from his buggy, the hernia came down. It was more painful than usual. It was reduced a short time after, but the pain continued, and he soon began to vomit. When seen by Dr. Hanna, five days after the hernia came down, the patient's abdomen was tympanitic, the vomiting had continued: the pain was slight, and in the five days the bowels had not moved. Examination revealed the inguinal canal apparently free. The patient presented the same symptoms when he came under my observation in the hospital, except that a small, hard nodule could be detected on the inner side of the right inguinal ring. The finger could pass freely into the canal without obstruction. This nodule was sensitive to pressure and very hard. The scrotum was full of fluid, as the patient said, from an old hydrocele.

Operation. Hernial sac opened, found empty, incision extended up into abdomen, and just below the inner pillar at the induration was found a knuckle of intestine passing from the seat of hernial sac through a very narrow opening into the hydrocele sac, as shown in Figs. 8 and 9. The abdomen contained a considerable quantity of serous fluid. Before the hydrocele sac was opened, the field was well packed with gauze and preparations made for a resection of the bowel. Hydrocele sac opened, contained a Littre hernia, involving four-fifths of the circumference of the bowel: it was gangrenous and perforated, and the hydrocele sac was full of very offensive pus and feces. Resection of five inches, end-to-end approximation with button, and mass returned into abdomen. Peritoneal cavity full of seropurulent fluid: incision left open and packed with gauze. Patient's condition when removed from the operating table very good. Within the next eight hours after operation he had six bowel movements, but his pulse began to increase. He had no pain, tenderness, tympanites nor vomiting. His expression became anxious and he died thirty hours after the operation from auto-intoxication.

We have in this case a striking illustration of the importance of operating where the symptoms of vomiting continue after the reduction of the hernia. Furthermore, we have an additional illustration of death from auto-intoxication from the absorption of the decomposed proteids that have been retained in the intestinal canal. In this case it could not be attributed to the thrombosed veins as they were resected.

TOWEL METHOD OF REPLACEMENT.

Surgeons of experience well know how difficult it is to replace the bowels after they have been out for a considerable time during an operation even when protected by hot applications. The causes of this difficulty are: 1. Usually before the operation the bowels are full of gas (tympanitic) from the diseased condition demanding the operation. 2. During the exposure the intestinal wall becomes edematous and a large transudation of fluid into the intestinal canal takes place. The bowel when eviscerated is light and its wall thin and pliable, in half an hour it becomes heavy and sodden, resembling sausage. These changes make it difficult to replace the intestine into the abdominal cavity. Some operators resort to puncture of the bowel to relieve the distention and thus facilitate the replacement. In a number of cases I have used the following method of returning

the bowel. Cover the entire intestinal mass with a hot towel, placing the edge of the towel inside the margin of the wound all the way around. This acts as an artificial abdominal wall and resembles an enormous ventral hernia with a large neck or opening. The operator and assistant then press or work the edge of the towel under the wall on all sides, with the fingers, at the same time elevating the abdominal wall with retractors, and thus force the mass down to a level with the abdomen. The reduction is effected in this manner as easily as a hernia is reduced after the ring has been enlarged. The sutures are then inserted and as they are tied the towel is gradually withdrawn.

I desire to thank Dr. F. S. Hartman for his assistance in the preparation of this article.

911 Venetian Building. Chicago.

TRAUMATIC STRICTURE OF THE VAGINA.

BAYARD HOLMES, M.D.

PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS OF CHICAGO.

A bride of three days consulted me on account of unendurable pain at the first attempt at sexual intercourse. She was a young woman of apparently perfect health. She said she had never been sick in her life and that she had worked constantly as a nurse for several years after taking training in a small hospital. In her girlhood she had fallen on a picket fence and injured the vagina and bladder, but she believed she had entirely recovered from that injury. At each menstrual period she bloated some but had no pain. There was always a rather long flow, sometimes lasting six or eight days. Clots were never seen. There had always been some leucorrhea. On making an examination the vagina was found closed just beyond the remnants of the hymen. A large tumor could be felt through the rectum about an inch and a half behind this stricture, and still further back the tumor verged into the uterus. The tumor was evidently cystic. Pressure upon it did not cause any discharge of its contents into the vagina, and was not painful. The case was pronounced one of stricture of the vagina with dilatation of posterior portion by discharges from the uterus.

She was operated on in my hospital the following day and the diagnosis confirmed. The probe was passed into a small opening in scar tissue at the bottom of the vagina, for half an inch, and then with the finger in the rectum and the sound in the bladder the vaginal wall divided. This move was repeated several times until at last the sound came into the cyst and about six ounces of pus-like fluid was discharged. The cavity was washed out. The ragged anterior portion of the vagina was then trimmed into a regular line. The posterior vaginal mucous membrane was loosened up from the bladder and rectum so that it could be brought forward and attached to the anterior portion. The line of suture was slightly elliptical extending farther back dorsally than ventrally. By the end of two weeks the union was complete and the vagina would admit the glass plug that measured an inch and a half in diameter. The dilated cervix of the uterus had contracted to about the normal size. Two months later the patient reported herself perfectly well.

This was an unusually easy case to treat. The distention of the posterior vagina gave loose tissue enough to bring forward and repair the vaginal defect. This defect seemed to be one and a half or two inches long.

BUST OF THE LATE PROFESSOR WILLIAM H. BYFORD.

PROFESSOR DELASKIE MILLER, in accepting the bust of Dr. Byford to be placed in Rush Medical College, paid the following tribute to the memory of his late colleague:

GENTLEMEN OF THE BOARD OF TRUSTEES AND OF THE FACULTY:

Ladies and Gentlemen: Obedient to the impulses of my own heart, I feel that I must do more than pronounce these formal words of acceptance and thanks for this valued memorial of Professor Byford. Moreover, the presence of so many who knew the original and appreciated his worth as a man, and his skill as a physician, constrains me to indulge my inclination.

As the years recede, men who are engrossed in the duties which are imposed upon them by the exactions of life's struggles, are hardly conscious of the changes that are constantly taking place around them, or if an event should arrest the attention, the impression is quite certain to be only of short duration. Still it remains true that the column of figures behind them which shadow forth the lapse of years is rapidly attaining altitude. It is well that this register of passing events is thus placed, for thus it may elude the vision for a time; were it otherwise, men would hardly go forward with the same intense interest in their vocations, or continue to exercise the same vigorous striving for high acquisitions, or to feel so constantly the stimulus of the same bright hopes.

Notwithstanding this pre-occupation, the lesson of experience which we and all should learn to heed, is, that one by one our comrades are dropping from the ranks, and when one whose characteristics are partially expressed by words like these—gentleness, goodness, uprightness—probity and preëminent ability has departed, it is most fitting that we should step aside from the onward rush of the tide of events and give expression to our appreciation of his character.

To be effective every delineation requires that attention be given to the environment. A landscape of forest, glen or rivulet without a suitable background, would be faulty. We must see the sky, the clouds, the distant mountain tops, the haze of the atmosphere, the decomposed sunlight giving the variegated coloration of morning or evening views, as well as the forest, the glen or the rivulet.

In presenting my subject to-day, it will therefore be to the purpose to sketch the environment of Dr. Byford's early life.

William Heath Byford was born March 20, 1817, in the hamlet of Eaton, Preble County, Ohio. Thus the year 1817 gives us the point of departure in this study. What was Ohio in 1817? The western tier of counties was a wilderness, broken only by occasional settlements. This was the frontier of civilization. Indiana had been a State but one year. Illinois, Michigan and Wisconsin were parts of the great Northwest Territory. Plato said: "That to know what a thing is, we must know what it is not," accepting the teaching of that wise man, I must use negatives mainly in expressing my present thought. In most places of that region the forests were so dense that the sun's rays could not penetrate to the earth. The roads were not improved, the stumps and other rubbish had not been removed in the isolated clearings. There were no railroads, no telegraph lines, there were no electric or gas lights; verily,

western Ohio was distinguished for the absence of all improvements which we think are essential for a comfortable existence. What a background does this present to us, on which to limn the outline of the evolution of a human life!

Some have emphasized the fact that the father of William was not wealthy. In this respect, I imagine, that his case was not peculiar. In the small communities of that time widely separated as they were in districts, wild as nature, he was rich who possessed health, habits of industry, integrity and the indomitable courage to look unappalled into the future. That I have not overdrawn the picture, may be inferred by the fact that while William was still in his infancy, the father was dissatisfied with the location, and in hope of improving his circumstances, he moved to another section of the country, also new, viz., the Falls of Ohio, now called New Albany. And again, in 1821, he removed to Martin County, Indiana. Here William began his career as a scholar. Here he had the advantages to be obtained in the public country school (whatever they might have been).

It was here that the father, Henry T. Byford, died, when William was nine years old. This bereavement compelled William to leave school, and at this tender age devote his time and strength to the aid of the widowed mother.

In acquiring his education, I am not aware that William ever had the advantages of a university, a literary college, an academy, a high school or even the district school, after he was nine years old.

It does seem that these were hard lines for the boy who was to become, though he knew it not, a most eminent physician and a leader of the profession in a metropolitan city. Some who have had the advantages which Harvard or Yale could offer, have in their life's work accomplished less than did this orphan boy.

At the age of thirteen he was apprenticed to a trade. At this trade he worked faithfully for six years, but he devoted the spare hours to study. Of his success as a student, under these circumstances, you shall judge. In four years he had acquired a thorough knowledge of the English language; he knew Latin, Greek and French. He had studied natural history, physiology and chemistry. At this period he determined to become a physician, and he applied his energy to study with such success that in 1838 he presented himself to the Board of Commissioners authorized by the statute to grant licenses to practice. He passed a satisfactory examination and received a certificate testifying that he was qualified to practice medicine and surgery.

He began the practice of medicine in Owensville, Ind., Aug. 8, 1838. In 1840 he moved to Mt. Vernon, Ind. He attended medical lectures in the Ohio Medical College, and received the degree of Doctor in Medicine in 1845.

In 1847 he performed the Cæsarean section, the most daring operation known to surgery, the history of which he wrote and published.

From this time forth he wrote numerous and valuable papers on a variety of medical subjects for the medical journals, which attracted the attention of the profession throughout the country. One paper, as I remember, was of unusual interest, and elicited a great deal of earnest discussion by the profession. It was on "Milk Sickness," a peculiar disease. The mortality was so great from this disease that it was

called by the historian of that time "a frightful pestilence." Its etiology was probably no better understood at that time than it is by the most learned physicians of the present day. I write from memory and am unable to give Dr. Byford's views of this disease, nor can I indicate the publication in which they were printed.

In 1850 he was appointed Professor of Anatomy in Evansville Medical College. Two years later he was transferred to the chair of Theory and Practice of Medicine in the same institution. During his connection with that college he was one of the editors of the *Evansville Medical Journal*.

He was elected Vice-President of the AMERICAN MEDICAL ASSOCIATION in May, 1857, and in the same year he was chosen to fill the chair of Obstetrics and Diseases of Women and Children in Rush Medical College.

For two years he was associate editor of the *Chicago Medical Journal*. After two years he retired from Rush Medical College, and united with other gentlemen in organizing and establishing the Chicago Medical College. In that institution he filled the chair of Obstetrics and Diseases of Women and Children.

He was a member of the American Gynecological Society, and in 1881 was elected its President.

Dr. Byford was active in the organization of the Woman's Medical College of Chicago, of which he was President, and to his personal influence and his valuable work as one of its professors, that institution was indebted for its well-known prosperity and acknowledged usefulness.

He was an active and zealous member of the Chicago Medical Society, and by the frequent contribution of papers on important subjects, and by his participation in the discussions in its meetings, he did much in raising the society to great usefulness.

Dr. Byford was requested to reorganize the Woman's Hospital of Chicago, at a time when its existence was threatened. He soon collected the forces and systematized the work in a manner that insured its permanence and capacity for greater usefulness. By his indefatigable exertions a new, substantial and capacious hospital building was erected. The benefits to the sick and suffering dispensed by the Woman's Hospital, under his efficient management, are beyond calculation.

It is no wonder that the friends of this hospital were greatly exercised and anxious regarding the future of its usefulness when Prof. W. H. Byford was stricken down. Even the Board of Lady Managers seemed not to realize for the time being that there was still connected with the medical staff another Byford. It is not out of place for me to say here that the Woman's Hospital maintains its high grade of usefulness.

Dr. Byford was the prime mover in the organization of the Chicago Gynecological Society, and he was its first President. The amount and quality of work done in this society will compare favorably with that of the best societies known. It still continues to produce abundant works of the highest scientific and practical value.

He was a life member of the British Gynecological Society.

I have alluded to the fertility of Dr. Byford's pen, but it was not limited to the production of contributions to the medical journals. In 1864 he published his work on "Chronic Inflammation and Displace-

ments of the Unimpregnated Uterus." In passing, I note that this was the first systematic medical work published by a Chicago author. At this time the author had acquired considerable reputation in the treatment of the diseases of women. To prove that he was a pioneer in this department of practice, it needs only to be stated that, owing to the novelty of procedure, there were eminent men in the profession not a few who endeavored to discourage the use of means which were necessary in making a diagnosis. Notably, of these, was the Professor of Obstetrics in the Medical School of St. George's Hospital, who insisted that this practice was of questionable propriety, and he did not hesitate to use, in condemnation of the practice, even more ungracious terms.

In 1866 Dr. Byford published his "Practice of Medicine and Surgery Applied to the Diseases and Accidents Incident to Women." This work has passed through successive editions, and is recognized as a standard text-book in the medical colleges.

In 1872 his work on Obstetrics was published. With justifiable pleasure the doctor related to his intimate friend an incident of his first visit to Europe. He called to pay his respects to the venerable Dr. McClintock, of Dublin. During the interview, Dr. McClintock went to his bookcase, saying to Dr. Byford, I wish to show you a work which I consider one of the best on the subject in my library, and then handed him Byford's Obstetrics.

By invitation, in 1879, Dr. Byford attended the annual meeting of the British Medical Association, and read an important paper on the use of ergot in the treatment of fibromyomata of the uterus.

Dr. Byford returned to Rush Medical College in March, 1879, and was elected to the chair of Gynecology, which he filled continuously till his demise, May 21, 1890.

As an operator he was deliberate and painstaking. No minutia of detail was too trivial to escape his attention, for he held that every item of detail was important, and to his care in these particulars must be attributed largely the secret of his success.

As a teacher he was accurate in every statement of scientific truth as he understood it. He was systematic in his arrangement of the subjects, and logical in his deductions. His vocabulary was ample and his words were well chosen. He never attempted unnecessary embellishment of style. He avoided everything in his lectures, either of word or act, which would tend in the least to divert the attention of the class from the elucidation of the subject under discussion. These were the qualities that made him the popular teacher that he was.

In his professional intercourse he was considerate and just. In his deportment no prospect of immediate advantage ever influenced him to swerve in the slightest degree from the line of rectitude. To such a man the printed code of medical ethics was useless. In the dignity of his manliness he rose above the technical limitations which that code would prescribe. To the young physicians he was generous to a degree that secured their confidence and captivated their affections.

Here I can not resist the temptation to introduce the estimate in which Professor Byford was held by an eminent member of the profession long years since.

In 1859, after Dr. Byford had withdrawn from his position in Rush Medical College and united with

other gentlemen for the purpose of organizing and establishing a new medical college in this city, in answer to a direct question, Dr. Daniel Brainard said to me: "Dr. Byford is a physician of uncommon ability."

These are expressive words, when we remember the time—when we consider the circumstances we are conscious that comment could add nothing to their force.

Now having reached this stage of my sketch, we find that Dr. Byford attained eminence and great reputation. He seems to stand alone, like a general in front of the long column of an army (if I may use the simile). Do you query: Who were Professor Byford's teachers? I answer, he had no teachers.

True, he took his degree from a legally organized medical college. But what were the opportunities for obtaining a superior medical education at that time in a western school? There were no clinics worthy the name. Of the didactic lectures, which were the principal, almost the only means of communicating knowledge in all the medical schools, I have only this to say: There are doctors present who are old enough to recall the appearance of the paper as the pages of the manuscript were turned, already venerable with age, having passed into the sear and yellow tint, from which the professors droned out their instructions. No, Dr. Byford had no teachers! He took his degree and at once stepped upon a plane, above and unknown to his confreres.

Were the story of Dr. Byford's life, which I have only briefly sketched, duly extended, we would be obliged so search far to find many analogous to his; in the obstacles which he overcame; in his usefulness in society and in the eminence which he achieved. I know of but one in any profession whose life presents a parallel, and of that life I need not rehearse the particulars. You all know it well, of course I refer to Abraham Lincoln, also, of Illinois.

The home life of Dr. Byford needs no words of praise. The most sacred word to the true man is, Home. This word includes all the real pleasures and joys of life. One who saw, and knew that home and the daily life in it, can affirm that the delicate graces and refinements of true affection resided there. It was a type of the house of "many mansions." In a sense there could be but a thin veil between that home and the "house not made with hands."

Dr. Byford had an abiding faith in the doctrines of the Christian religion. With a congenial friend he never wearied of conversation on the influence which these doctrines exerted in the formation of character; in elevating thought; in stimulating aspirations for the highest good; believing, as he did that the surest way to secure the greatest amount of pleasure in life was by practicing all the virtues implied in the "golden rule." He enjoyed the solemn worship with the congregation, but public worship was not a necessity to him; the graces of his belief shone brightly in the acts of his daily life. With a full consciousness of the solemn import of the words and with a reverent awe, I would class Dr. Byford with those who in the sermon on the mount are promised the blessing; for they "are pure in heart."

Dr. Byford possessed the spirit of genuine devotion. He could offer acceptable worship when alone in the grand cathedral of nature. Standing under the arch of the blue canopy in

"The broad blessed light, in the perfect air,
By the rippling tide, the tree, the meadow, the flower,
Listening to the symphonies of the living breeze,
And in the midst, in the hour of faith,
He could see God's beautiful and eternal right hand."

During the latter years of Dr. Byford's life, he was a great sufferer from sudden attacks of severe pain in the region of the heart, attended with difficult breathing. These attacks became gradually more frequent and more painful, ordinary exercise was liable to excite an attack, so much so, that about a week before his death he announced his determination to decline all cases which would require operative procedure.

The diagnosis of his case was "ossification of the coronary arteries."

In the evening of May 20 he took a bath, as was his custom, and retired; about midnight he was seized with an attack of unusual severity.

"These were the parting pangs which nature feels
When anguish rends the heart strings."

The nearest physician was called hastily, he administered an anodyne, and the son, Dr. Henry T. Byford, was summoned by telephone. The doctor responded promptly, but when he reached the bedside his father was unconscious, and he remained in that state till he breathed his last at 2 o'clock A. M., May 21, 1890.

The funeral was largely attended by the physicians of the city, and by other mourning friends.

It is a coincidence that these services have been held on the anniversary of Dr. Byford's death.

NEW INSTRUMENTS.

A DOUBLE STOMACH TUBE.

BY F. B. TURCK, M.D.

CHICAGO.

This new apparatus is similar to the needle-douche and the gastric motor meter. It consists of a thin rubber bag connected with a double tube, and has been devised by me for the purpose of diagnosis and treatment. As stated before, this is simply an addition to the double tube, known as the needle-douche, which I first used two years ago, and which was first shown at the International Medical Congress at Rome in 1894, and later at the meeting of the AMERICAN MEDICAL ASSOCIATION at Baltimore, May 7, 1895. Further reports on its uses and advantages were published in the *Therapeutic Gazette*, May 22, 1895, in an article on "Chronic Glandular Gastritis." Again, reference has been made to the use of the double tube in an article "Methods of Diagnosis and Therapeutics in Diseases of the Stomach," published in the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, June 22, 1895. Previous to this, May 21, 1895, I demonstrated it before the New York Academy of Medicine. The lecture was published in the *American Medical and Surgical Bulletin*, July 1, 1895.

The use of the double tube is not of recent date. It is an old method which has been common property for some years. Therefore no originality can be claimed for the simple use of the double or recurrent tube. The distinctive features which I was the first to bring out, as far as I know, are:

Two single tubes of different caliber attached to one another side by side. The one of smaller caliber reaches to the cardia only, the larger extends to the great curvature. The short smaller tube, which reaches to the cardia only, was made smaller so as to,

in some degree, equalize the relation between the inflow and outflow of the water, and also for direct treatment of the stomach wall.

When a small perforated ball is attached to the shorter smaller tube, it is used as a needle-douch for forced irrigation. Furthermore, it was found of great value (as previously reported) in using hot and cold water alternately. A fine spray needle-douche projected against the wall of the stomach acts as a vasomotor and a muscular stimulant, similar to a rain- or fan-douche used on the surface of the body. This belongs to the hydro-therapeutics of the stomach.

By leaving off the small ball the same tube has been used with the nebulizer which I introduced for the treatment of the stomach walls with oil of cloves and other medicaments.

I have found this arrangement of the double tube (small caliber reaching to the cardia, large caliber extending to the great curvature) very valuable for a number of purposes. Others have evidently recognized it, and have adopted my modification of the old double or recurrent tube. (Vide Hemmeter, *New York Medical Journal*, Dec. 28, 1895.)

This new apparatus may also be used as a gastric motor meter, an instrument which I first demonstrated before the AMERICAN MEDICAL ASSOCIATION at Baltimore, May 7, 1895. Previously it was shown in a special course of lectures in the Post-Graduate Medical School, Chicago, September, 1894. Also at the meeting of the County Medical Association, Philadelphia, May, 1895.

In this new apparatus the smaller tube leads to the upper part (the opening) of the thin rubber bag, the larger tube reaches to the bottom of the bag, similar to the tubes and bag of my gastric motor meter and needle-douche. When the bag is collapsed it fits very closely to the tubing and does not considerably enlarge it, so that it readily passes into the stomach.

USES OF THE APPARATUS.

For purposes of diagnosis. Water is introduced into the bag through the smaller tube from an elevated graduated reservoir. The current is rapidly carried into the bag, the other tube acting as a vent. The elasticity and distensibility of the stomach can be determined by the degree of distention produced which may readily be seen on the graduated elevated reservoir.

The stomach may be mapped out: 1. By percussion. 2. By inspection with the electric light. By introducing the electric light into the bag when it is filled with cold water, a very much higher candle power can be used than ordinarily. Thus the illuminating power is increased without danger of overheating, since the constant flow of cold water prevents this. The partly spherical body of water contained in the bag, the bulk of water acting as a refracting medium, greatly increases the power of the light. 3. By palpation. By using the gyromele the stomach can be mapped out most accurately by palpation.

This will give the most positive evidence of the exact location. By using the gyromele when the bag is empty it can be placed into any part of the stomach desired, the pyloric extremity or cardia. This is done by introducing the cable through one of the tubes and passing it along to the desired part. The pylorus can be dragged down and palpated in many cases, by introducing large quantities of water. This one fact alone makes it a valuable aid in early diagnosis of carcinoma of the pylorus. When air is introduced with the water the degree of increased or decreased motility of the stomach can be determined. One of the tubes is closed and the other is connected with a manometer. I have previously reported on the uses of the gastric motor meter, by the use of air, or water, or both. It has been found that a small quantity of water, 100 to 200 c.c. stimulates contractions, especially in a healthy stomach. When over-distension occurs, as by the use of a liter of water, or more, it rather interferes with the motility, on account of the greatly increased bulk and weight.

Treatment.—The use of this apparatus for treatment is chiefly in cases of congestion of the gastric and mesenteric vessels. By introducing a constant stream of hot water—105° F., sometimes even 110° F.—an even constant temperature is kept up. It is especially beneficial in cases of chronic gastritis attended with gastralgia, due to congestion. It may also be used in cases of prolonged operation upon the viscera, to prevent shock. Its value in cases of shock is due to the fact that not only the gastric and portal vessels are affected by the hot water, but also the superior mesenteric, which lie beneath it. The important use of this method is that a constant and even temperature can be controlled by the continuous flow, and that hot and cold water can be used alternately. In cases of sluggish circulation of the stomach, or deficiency in musculature and secretion, the stimulating effect of alternating hot and cold water can here be readily utilized.

The advantages are:

1. The hot or cold water treatment can be continuous. The water does not come in contact with the mucous membrane, therefore secretions and particles of food-stuff necessary for nutrition are not removed.
2. The water can be aspirated readily without endangering the mucous wall.
3. The amount of water retained in the stomach can be regulated at will.
4. By using a large oval-shaped bag, distended, great force can be used in projecting a stream against the wall with the spray or needle-douche, stimulating the gastric vessels and musculature. The needle-douche can be used for a considerable time under great pressure. As fast as the water is projected it can be aspirated. There is no obstruction to the rapid withdrawal of the water.

No. 1, The Plaza.

SOCIETY PROCEEDINGS.

Association of American Anatomists.

Meeting held in Philadelphia, Dec. 27 and 28, 1895.

THE DUTY OF THE MEDICAL PROFESSION TO CIVILIZATION AND TO SCIENCE.

DR. THOMAS DWIGHT, of Boston, Mass., in his opening address as President spoke of the horror which the general public have for human dissection, and the aversion of the popular mind to this very necessary part of medical research. This prejudice he believed was founded, first, in the popular belief

that sepulchers were violated: and second, that the remains were subjected to wanton insult.

It is idle to hope that while human nature remains as it is this aversion to dissection will ever disappear. Our wisest course is to recognize it and to soften it by removing all just cause of complaint. It should be made clear to the public that dissection can and should be followed by decent burial. I, myself, would go so far as to have the bodies of Protestants and Catholics buried in their respective cemeteries when the creed of the deceased is known. It should also be understood that no wanton insult is permitted in reputable schools. The policy which will lead to the most satisfactory results is one of complete openness. Above all, we should avoid a timidity which shirks discussion of this topic. When we shall show so clearly as to carry conviction, that we have nothing to conceal, a great step will have been taken. A radical defect in the laws of many States otherwise well drawn, is that the delivery to medical schools of unclaimed bodies is optional with superintendents, boards of trustees and municipal authorities. The result of this is that those in authority very naturally hesitate to do anything for the advancement of science which not only can be of no possible advantage to themselves, but may involve them in serious difficulties.

German anatomists have recently adopted a report prepared in company with the representatives of other European countries, prepared with the idea of establishing a more satisfactory, and at the same time more scientific nomenclature than is at present in use. It is for us to decide whether their report is satisfactory, and if so, whether we shall join hands with our foreign colleagues, or if such is not the case, whether we can devise an American nomenclature which shall be so much better as to be distinctly superior to that at present in use.

ANATOMIC MATERIAL AND ITS PRESERVATION.

A committee of three appointed by the Association of American Anatomists to investigate this subject made their report at the meeting held Dec. 27, 1895, as follows: In response to a circular which was sent to a number of teachers of anatomy, not only in this country but abroad, in which a series of questions were asked, full answers were secured from the majority. This letter was sent to the professors of anatomy in 148 colleges in the United States, twenty-five in foreign countries, and twenty-five copies were sent to the medical journals in this country and Europe.

1. Anatomic material is received wholly under the provisions of the law in thirty States and countries, in part by law in seven and without law in five.

2. The provisions of the law were satisfactorily complied with in ten, fairly so in ten, not satisfactorily in twelve, and no replies were given in ten. In eight the provisions of the law were stated to be obligatory and in six the provisions were optional.

3. As to the condition in which the anatomic material was received, in twenty instances it was good, in twenty-one fair, and in one bad.

4. As to the disposition of the remains, in twenty-seven institutions they were reported buried, in ten cremated, and in four thrown away.

5. The agents employed in the preservation of subjects were various, and employed in a variety of combinations. Carbolic acid stood first, and was found to be especially useful in combination with other agents. Glycerin was the ingredient of next importance. It was also employed in combination. Arsenic was the next most popular, especially in combination with other substances. Chloral hydrate, the chlorid of zinc and the bichlorid of mercury came next in the list. Alcohol either pure or in combination, carbonate of potassium, the bicarbonate of sodium, chlorid of sodium, methyl spirit, formalin, nitrate of potassium, brown sugar, and boric acid were reported as successfully used.

The preservation of subjects by cold storage was reported in five instances. Some of the agents above noted were used in combination to preserve the subject which had been kept in cold storage, after it had been placed upon the table for dissection. It was found that the subject would keep indefinitely. A solution of the chlorid of zinc of neutral reaction, 50 per cent, in strength, was found to successfully preserve subjects, but it has the objection of hardening tissues and causing a change of color. If subjects have been immersed for a long time in a solution of common salt it has been found advantageous to soak them in water for twenty-four or forty-eight hours in order to soften the tissue. A number of useful formulæ for the preservation of subjects were forwarded to the committee, such as Wickersheim's, containing alum nine parts, chlorid of sodium twenty-five, nitrate of potassium twelve, carbonate of potassium sixty, arsenious acid ten; when cool filter and to

ten parts of the liquid thus obtained add one part of methyl alcohol and four parts of glycerin. Van Vetter's formula, seven parts of glycerin, one part of brown sugar and one-half part of nitrate of potassium. Langer's formula, 100 parts of glycerin, fifteen parts carbolic acid and eleven parts of alcohol; and Emperonne's formula, chloral hydrate 500 grs., glycerin 2½ liters, and distilled water.

6. Injections were made in two institutions in the heart, in nineteen in the common carotid artery, and in six in the common femoral artery.

7. The cost of receiving and preserving material was stated to have been from one to twenty-five dollars per subject.

8. In fifteen cases the supply of material was stated to be sufficient and in fifteen insufficient. The number of students who were assigned to each subject varied from four to sixteen.

The committee, consisting of Drs. J. Ewing Mears of Philadelphia, J. D. Bryant of New York and Thomas Dwight of Boston, Mass., heartily recommend that, 1, a combined effort should be made by the medical profession to secure the enactment of laws which will provide for the proper supply of anatomic material to medical colleges; 2, that an effort should be made to place before the public the great necessity which exists for the proper use of dead bodies in providing instruction for students of medicine, and the ample protection afforded the citizens of every State by the enactment of laws which will regulate the supply of anatomic material. The committee believe that the cold storage method of preservation in combination with the injection of chemic agents especially adapted for that purpose, affords the best method at present known. The great objection to formalin and alcohol is that they are both too expensive.

CONCLUSIONS.

1. Anatomic material for the promotion of medical science should be obtained wholly under legal enactment. The provisions of the law should be compulsory upon all officers of the State and county institutions and municipal governments.

2. Of the anatomic laws which are in force in this country the committee are of the opinion that the law of the State of Pennsylvania is the best.

3. The committee believe that it would contribute to the best interests of anatomic teaching in this country if action were taken by this Association to secure the enactment in every State of a law controlling the collection and distribution of anatomic material, and it heartily recommends such action.

4. While many of the agents reported in the communications which have been received have been long in use and have been to a greater or less extent employed successfully, the committee feel that no definite conclusions can as yet be drawn in regard to that perfect method as well as the securing of the best results in dissection, which it is hoped to secure. The preservation by means of cold storage approaches nearest to the perfect method, and it should be arranged upon a plan which will admit of the retention of subjects for a long time under the influence of a low temperature during dissection.

Dr. B. G. WILDER, in discussing the report of this committee, said that after an experience of twenty-seven years, we are wedded to the use of alcohol. Brain tissue, we find, is best preserved by a combination of formalin, bichlorid and salt. For muscles and viscera, alcohol is the best preservative. There are two objections to its use, first, the cost, and second, the property it has of bleaching the tissues.

Dr. G. B. HUNTINGTON fully agreed with Dr. Wilder in regard to alcohol. He recommended also the cold storage plan, which after an experience of three years has been found to give good results. Any injections should be made before freezing. Immersion in cold water is the best method of removing the ice from the body, and hastens the uniform melting of the parts. Arsenite of soda was used chiefly for washing the blood out of the body. Injections were made into the carotid artery, and the blood was allowed to flow until the water which made its escape was no longer tinted with blood.

Dr. BEVAN said that he had had excellent results with the combination of cold storage and a preliminary injection of alcohol, glycerin and bichlorid. In handling bodies while in cold storage, he made use of a pair of tongs, which can be made by any blacksmith for about one dollar in such a way as to fit into the external auditory meatus of each side. He has found a solution of formalin and Müller's fluid to be useful in the preservation of brain tissues; the substance so prepared hardens rapidly, and may be used for class demonstration to within three days; the color is well preserved, and it is possible to distinguish the gray and white matter at a distance of fifty feet. He uses a 5 per cent. solution of formalin in Müller's fluid, enough of the solution being employed to immerse the specimen.

A CONTRIBUTION TO THE MYOLOGY OF LEMUR BRUNUS.

Dr. GEORGE S. HUNTINGTON, of New York City, read an interesting communication on this subject. He confined his attention to the muscles of the trunk, pectoral girdle, and upper extremity. His results differ in many respects from the descriptions published by Murie and Mivart in their memoir of the anatomy of the lemuroidea and others. The paper dealt especially with the following points which have hitherto been undescribed.

1. The presence of an axillary arch from latissimus dorsi to the pectoral insertion replacing the cutaneous muscular slips described by Murie and Mivart.

2. The peculiarities of the humeral attachment of the pectorals which may be arranged as follows: *a*, the connection as already stated with a slip from the latiss. dorsi reproducing the condition found in a distinct variety of the humeral axillary arch. *b*, the connection of the abdominal division of the pectoralis major with the pectoralis minor at its insertion into lateral humeral ridge. *c*, folding of insertion tendon of the sternal division of superficial pectoral. *d*, insertion of clavicular portion into superficial aspect of sternal tendon and its fusion with the deltoid. All the conditions referred to can be properly regarded as presenting strong simian and anthropoid affinities.

3. The coraco-brachialis presented a division into an upper, middle, and lower parts, the latter was inserted into the root of supracondylar arch. The musculo-cutaneous nerve perforated the middle division.

4. The presence of a large and distinct epitrochleo-anconeus from the supracondylar process to the internal condyle and the ulnar margin of the olecranon.

5. The union of the brachialis anticus and the lateral head of the triceps, both extending to the head of the humerus and arising from the outer aspect of the bone.

6. Among the trunk muscles the arrangement of the supracostalis was especially to be noted, extending from the cartilage of the first rib to the third, fourth and fifth cartilages at their juncture with the sternum.

The entire group of deep thoracic muscles presented a typical carnivore aspect. The supracostalis, thoracic extension of the rectus abdominis to the first rib, a continuation of the serratus anticus with the levator scapulae, the thoracic extension of the scalene group and its relation to the external oblique all conform almost absolutely with the type presented by a plantigrade carnivore as *Taxidea Americana*. On the other hand the pectoral girdle and brachial muscles conform to the simian type. Thus far lemur brunus is especially marked in the arrangement of the pectoral group.

In the abdominal muscle groups the arrangement of the external oblique aponeurosis clearly foreshadows the structure found in the higher primates, especially in relation to the construction of the external abdominal ring, Gimbernat's ligament and the triangular ligament of human anatomy.

HISTORY OF THE CILIARY MUSCLE.

Dr. FRANK BAKER of Washington, D. C., after a careful review of the literature of this subject has found that the two portions of this muscle, the fibers of one part of which are directed meridianally along the eyeball and the other with fibers arranged equatorially have been named after observers who were not strictly the first to describe them. Thus the portion, which has been called Müller's annular muscle, has received its name from the description which Heinrich Müller of Würzburg gave of it in 1857. Portions which have their fibers arranged meridianally were often called Brücke's or Bowman's muscle, under the impression that the discovery or first description of it belonged to one or both of these anatomists. Bowman described the ciliary muscle in his lectures on parts concerned in operations on the eye published in 1849, and Brücke called this muscle the tensor choroideae in a paper read before the Berliner Physikalischen Gesellschaft, in May 1846. Of the two descriptions that of Bowman's is the best. Bowman made several other publications on this subject. In 1844 he published a series of lectures in the *Boston Medical and Surgical Journal*; he speaks of the ciliary muscle as being composed of muscular fibers lying within the ciliary body. He supposed the striations of the orbicularis ciliaris to be tendinous. Before either of these observers wrote, however, the ciliary muscle was described and named by an American, Dr. William Clay Wallace, who published an article in *Silliman's Journal* in 1835. Dr. Wallace also published several other articles on this subject. In his treatise on the eye, New York, 1839, he mentions the ciliary body as containing muscular fibers. Also in 1844 in a series of lectures published in the *Boston Medical and Surgical Journal*, he speaks of the ciliary muscle as being composed of muscular fibers lying

within the ciliary body. He supposed the striations of the orbiculus ciliaris to be tendinous. Dr. Wallace also goes in the subject at considerable length in his lectures on myopia. *Boston Medical and Surgical Journal*, 1844, xxx, 288. See also the same author in the *London Medical Gazette*, 1842-43, 1, 412.

Among the earlier authors, there are also several who appear to have recognized the muscular nature of the so-called ciliary ligament. Even Eustachius, who lived from 1510 to 1574, had some divination of the muscular character of these fibers although he was unable to demonstrate them by the means in his power. Fallopius corrects him and calls it a ligament. Plempius (*Vopiscus Fortunatus*), *Ophthalmographia*, Amsterdam, 1632, p. 169, also describes this structure. Wm. Briggs, *Ophthalmographia*, 1686, speaks of it as possessing muscular fibers that change the form of the lens. G. Bidloo, "*Anatomia humani corporis*," Amsterd., 1685, and Descartes "*L'Homme de Rene*," 1664, describes this structure at some length and present a number of drawings illustrating the part.

It is interesting in this way to recall that the real nature of this part of the anatomy of the eye was not altogether unsuspected by the early anatomists, and that all the credit for an early description of this ciliary muscle is not entirely due to the men whose names the several parts bear.

ABSENCE OF THE FIBROUS PERICARDIUM, OF THE LEFT SIDE.

DR. ADDINELL HEWSON, of Philadelphia, presented an interesting specimen of this condition before the meeting. He had found it in the dissecting room of the Jefferson College. The specimen was removed from an Englishman by birth, aged 54 years, who had been an inmate of an insane asylum for four years previous to his death. By occupation he had been a scrivener. There was distinct absence of the fibrous pericardium on the left side and an adherence between the apex of the left ventricle and the lower anterior margin of the left lobe of the lung. The specimen showed in front the pleura enclosing the internal mammary artery and the left phrenic nerve displaced anteriorly from its normal position. An incision had been made in the median line to expose the vessels. The aorta practically had no arch and was near the median line. The innominate artery was wanting. The subclavian artery on the left side was found at the highest part of the arch. There was a wide space between the subclavian artery at its origin and the point where it crossed the first rib. The vena azygos major made a very decided arch coursing over the right half of the chest wall. While the patient had been confined in the asylum he had been in the habit of sitting with his knees drawn up and his head between his knees. This position being the one assumed by him for the most part may account for the adhesions which were present. The course of the phrenic nerve on the left side was normal. The posterior veins were inside of the posterior fold of the pericardium.

THE DESCRIPTIVE ANATOMY OF THE HUMAN HEART.

DR. WILLIAM KEILLER, M.D., F.R.C.S., Edin., of Galveston, Texas, read a paper on this subject. He used a mass of gelatin injected into the common carotid artery or the femoral artery for the preparation of his specimens, and he finds that when the heart has been so prepared it follows in all essential particulars the description of his model. Thus viewed the heart is an irregular four-sided pyramid whose base rests on the diaphragm and whose apex has been removed to afford attachments for the ascending trunks of the great vessels. It presents for examination five surfaces (including the base), a number of borders separating these, an anatomic apex and a clinical apex. The anterior surface is triangular in shape. In sagittal mesial section it is parallel with the sternum. It includes the greater part of the right ventricle, portions of the left ventricle, the left auricular appendix, the entire right appendix, and part of the right auricle. Its superior angle marks the anatomic apex and here the surface merges in the anterior walls of the aorta and pulmonary artery. Its left inferior angle forms the clinical apex. Separated from it by the pericardium are the margins of the lungs and pleura, the sterno pericardial ligaments, triangularis sterni, internal mammary vessels and sternum. The right surface is markedly convex, quadrilateral, lies almost vertically, and is directed toward the right. It includes the greater part of the right auricle. Its anterior, posterior and inferior borders are only slightly rounded, and are therefore fairly well defined. At its superior extremity the surface blends with the wall of the superior vena cava, and at its posterior inferior angle it is similarly related to the inferior vena cava. It is separated by the pericardium from the right phrenic nerve and vessels, the pleura and inner surface of the right lung.

The left surface is a complex triangular area directed mainly upward and toward the left. It includes about one half of the

free surface of the left ventricle and the left auricular appendix. It presents the proximal extremities of the descending branch of the left coronary artery and great cardiac vein, the marginal and transverse branches of the same artery and the posterior cardiac and coronary veins. It is separated by the pericardium from the left phrenic nerve and vessels, the left pleura surface of the left lung. The posterior surface (dorsal surface) is called the base in text-book descriptions. It is four-sided, rather narrower above than below, is convex, vertical and directed backward. It is formed by the left auricle and by the portion of the right auricle which joins the two venae cavae behind. It presents the opening of the coronary vein (right and left), the great coronary vein and coronary sinus and the oblique vein of Marshall which runs down over the sinus to enter the left extremity of the coronary sinus. It is only partially invested by the serous layer of the pericardium—it is so separated by the pericardium from the bronchi, esophagus, vagi, descending aorta, vena azygos major and thoracic duct. The inferior surface (diaphragmatic surface or base) is quadrilateral, slightly convex, or almost flat when the ventricle contains blood. It is formed by a small portion of the right auricle and the opening of the inferior vena cava; the rest of the surface being about equally divided between the right and left ventricles. In addition to the inferior caval opening it presents the inferior extremities of the right (anterior) and left (posterior) interventricular grooves with the right coronary artery embedded in the former and the coronary sinus in the latter. Crossing it diagonally is the inferior interventricular groove with the descending branch of the anterior or right coronary artery and middle cardiac vein. The posterior cardiac vein runs along its posterior border. The apex of the pyramid is formed by the aorta, pulmonary artery and superior vena cava. These structures arise from the heart on a level with the upper margin of the third costo-sternal articulation extending an inch and a half to the left and one inch to the right of the middle line. The clinical apex is indicated by a point between the fifth and sixth ribs three and one-half inches to the left of the middle line. The antero-inferior border may be indicated on the chest wall by an oblique line extending from the clinical apex on the left across and slightly upward to a point one inch to the right of the middle line at the level of the sixth chondro-sternal articulation. Along this line the cardiac blends insensibly with the hepatic dullness. On a level with the fourth chondro-sternal articulation the area of the heart's dullness extends three inches to the left and one and three-quarter inches to the right of the middle line. The author suggests the following changes in the cardiac nomenclature in accordance with the above description. Thus the interventricular grooves are seen to be superior and inferior, the right coronary artery might be called anterior, and its branches respectively infundibular (as at present), right ventricular (now marginal), and inferior interventricular (now descending); the left coronary artery would be better named posterior and its branches superior interventricular (now transverse).

NOMENCLATURE OF NERVE CELLS.

DR. FRANK BAKER, of Washington, D. C., spoke on this subject. He regarded the term *neure* as the best name to use in describing these cells, because the word lends itself readily to combinations. Thus cells which form nerve roots might be called *rhizoneures* and cells of the cerebro-spinal axis might be called *axoneures*. If necessary these cells can be divided into other groups. Short path cells might be called *zigoneures* or commissural cells, and the long path cells of the cortical surface might be called *macrodromoneures*. In this way sensory fibers might be called *esthenoneures*. Other cells which have their origin in the spinal cord and are especially connected with the muscles might be called *dynamoneures*. The term proposed by Kolliker, or *neurodendron*, is too long. Other neurologists, among them Dr. Fish, prefer the term *neurosite*. As neurologists and psychologists are giving considerable attention to this subject it is reasonable to suppose that a better terminology will be adopted than the one now in use.

THE CEREBRAL FISSURES OF TWO PHILOSOPHERS.

DR. B. G. WILDER, of Ithaca, N. Y., presented a paper on this subject illustrated by specimens and a number of photographs. The paper referred to Chauncey Wright of Cambridge, a philosophic writer, critic and mathematician, and James Edward Oliver, Professor of Mathematics in Cornell University. The brain of the former was very different from the average pattern, and the two brains presented a distinct contrast, probably due to the greater activity and larger breadth of the former's scientific research. The reputation of the former was wider and better known than that of Oliver. One peculiarity of both brains was the simplicity of structure. The writer

called attention to the fact that there was no decided standard of comparison for the normal adult American brain, and he suggested that the members of the Association unite in an effort to secure some such standard.

THE HUMAN PAROCCIPITAL FISSURE—SHOULD IT BE SO RECOGNIZED AND DESIGNATED?

DR. B. G. WILDER, of Ithaca, New York, read a paper on this subject. Ten years ago the same writer suggested that the occipital portion of the long fissure called intra-parietal by Turner, inter-parietal by Ecker, and parietal by Pansch, be regarded as a distinct fissure under the title paroccipital, referring to its constant and marked relation to the dorsal end of the occipital (parieto-occipital). The "U" shaped area between the two or first annectant gyrus he proposed to call the paroccipital gyrus. The grounds for this suggestion have been given in the reference "Handbook of the Medical Sciences," VII, 155, as follows:

"1, in about half the cases examined by the writer there are two fissures separated by an isthmus of greater or less width: 2, when the two are continuous there is always a vadium (shallow) at the point corresponding to the isthmus: 3, each of the two portions, whether separate or continuous, is usually deepest at or near its middle: 4, at their first appearance in the fetus they are always completely independent. While this division is recognized by some observers it is thought needless by others and has not as yet received the sanction of the German Committee on Anatomical Nomenclature." The present paper was intended to review all the accessible literature on the subject as well as the material accumulated by Dr. Wilder in the interval, especially comparing these parts with similar fissures found in apes and monkeys.

On practical grounds the writer believes that the fissure should be recognized and called the paroccipital division of a "fissural complex." Among eight educated persons the isthmus occurred seven times in all but one on the right side. In only one case did the isthmus occur on the left side and not on the right, and that was the case of an insane Swiss patient.

PRACTICAL HISTOLOGY FOR LARGE CLASSES.

DR. CHARLES S. MINOT, of Boston, Mass., spoke as follows:

We have given up entirely allowing students to make their own preparations and we find the change to be an advantageous one. Every student is obliged to make a perfect drawing of each preparation and the drawing is judged on its accuracy. The geometric faculty is especially developed. In the second half year they are given practical work, and they then begin the study of the embryo. In commencing the work they are given specimens of the liver, heart, spleen, etc., instead of beginning with a connective tissue, a piece of bone or the like. We find it an advantage to teach embryology as a help to anatomy, and as offering an explanation to a great many relations that would otherwise be obscure.

SOME NOVEL METHODS OF DESCRIPTION OF THE HUMAN SKULL.

DR. HARRISON ALLEN, of Philadelphia, in his remarks upon this subject said:

My method is to secure a formula for each skull. I begin with the supra-orbital ridge, and draw a line between this point and the outer part of the external auditory process. The nasal bone may be divided into three parts, the upper part, the frontal; the main portion, the maxillary; and the third part, the pre-maxillary. In the human skull the third portion is not well defined. The frontal portion is very variable. Holding the bone in such a position as to examine it in profile it is possible to tell the proximal from the distal portion. The latter it is well to call the radix, and below that the salient. Variations in these portions serve to identify the individual. In two skulls of Sandwich Islanders which Dr. Allen presented, the one had a well-developed incisor crest, and the other had not. The anterior nasal spine is simply the end of the incisor crest. It has received the name of infantile, but Dr. Allen prefers the word pavidomorphie. The writer believes that the hard palate has not received the attention which it deserves in its posterior part. In negroes the middle lacerated foramen is very much narrowed and is frequently closed. The temporal fossa may be divided into two parts, the fronto-temporal ridge, and parieto-temporal. They are distinctly different. The former is very apt to be closed and is very rarely continuous with the same line as the parieto-temporal. No two skulls show a similar arrangement. In a study of the temporal bone the remains of a suture is sometimes found between the squamous and petrous portion. To the lower portion of this suture the name retro-tympanic has been proposed. In speaking of the lachrymal bones Dr. Allen said that scarcely any portion of the lachrymal bone is in advance of the crest. In the North

American Indian, and in the Sandwich Islander they are apt to be very small.

OBSERVATIONS ON THE FOSSA CAPITIS AND A TUBERCLE IN THE TROCHANTERIC FOSSA.

DR. F. J. BROCKWAY, of New York City, presented a carefully prepared paper on this subject. The fossa capitis which in the human femur is found at the extremity of that bone and gives attachment to the ligamentum teres, presents ordinarily a well-marked depression. In certain of the lower animals this depression does not exist. The ligamentum teres and the fossa capitis are absent in the elephant, hyrax, rhinoceros, tapir, hippopotamus, hedge-hog, seal, sea otter and walrus. They are absent in the monotremes, echidna and ornithorynchus; of the marsupials, the great kangaroo; of the edentates, the three and two sloth anteater. It is also lacking in one rodent and in one of the insectivora, etc. While a study of comparative anatomy frequently leads to valuable deductions, as to the function of parts of human anatomy, the writer dealt more especially with the human femora. He examined 900 human femora, of which the pedigree of over 400 was known. Moser in his article in Schwalbe's Arbeiten, vol. II, p. 36, says that only one-half of the fossa capitis that he examined presented vascular foramina. Dr. Brockway, however, found that in the 900 adult specimens which he examined, 84 per cent. presented these vascular openings. Twenty-six specimens (2.8 per cent.) presented no fossa at all, and in five cases there was a distinct tubercle in place of a fossa for the insertion of the ligamentum teres. In five cases there were double fossae occurring on one head. In two cases there was a combination of a fossa and a separate tubercle on the same head. In thirty-six cases the fetal condition persisted, *i. e.*, there was a fossa and a distinct postero-inferior groove descending nearly to the margin of the articular surface, and always pointing toward the line passing up from the lesser trochanter to the inferior border of the neck of the femur. Thus it is possible to determine to which side of the body the femur belongs by noting the direction of this groove: holding the fossa facing the observer the groove points to the side to which it belongs. Twenty-eight cases showed the presence of a fossa and a connected tubercle. The ligamentum teres is not inserted into the whole floor of the fossa, but into its upper half and upper margin. The lower part of the floor is free and the ligamentum teres simply rests upon it. Therefore, the vascular foramina are usually confined to the deepest and lowest portions of the fossa. The synovial membrane has a more extensive insertion than the ligament proper. The author described three types of the fossa: first, oval; second, triangular, and third, round. They are all practically the same whether they contain vascular foramina or not. The most common type of all is the oval form (45 per cent.); the next most common the triangular form (34 per cent.), and finally the round type (21 per cent.). Old people are apt to have shallow fossae, but their foramina are not more apt to be absent than in adult life. Out of twenty-two people over 60, thirteen had shallow fossae. The character of the foramina and fossae are not symmetrical on both sides. Out of the 900 bones examined only four could be called "pilastered." Twenty-eight specimens showed a good third trochanter (3 per cent.) not counting an exaggerated gluteal line. Six of these showed also a tubercle in a digital fossa. From a study of these specimens the linea quadrati would seem to be a myth, as Dr. Brockway has never seen it as a distinct line representing the full length of attachment for the quadratus femoris.

DR. D. S. LAMB, of Washington, D. C., showed a colored sketch illustrating

A CASE OF POLYORCHIS.

There were three testicles in the right scrotum and one in the left. They varied somewhat in size, but showed nothing abnormal in the texture of each. Three cords could be distinctly seen and felt passing separately through the external abdominal ring. The patient was a male, white, aged 45; well developed and enjoyed good health. He was a widower with two children. He has offered to submit to operation if sufficient remuneration was offered. A comparatively small number of cases of supernumerary testicles have been reported. A number of them, if not the majority, have been questionable. Armstrong, Blumener, Bulaboff, Hauser, Hewitt, Hough, Jacobovics, Kennow, Hetard, MacCann, McElmoil, Mercklin, Pranken, Sibbern, Stewart and Vanchrin have reported cases. Dr. Hewitt's case seems to be well authenticated and is as follows: The patient was a soldier with two distinct testicles and cords in the left scrotum. The cords united before entering the abdominal ring. This man is alive at the present time and the condition has existed since birth.

DR. LAMB also presented a "Note on the Appearance of a Unilateral Tuberosity in Place of the Trochanteric Fossa," with specimen.

SELECTIONS.

Recent Contributions to the Etiology of Malignant Tumors. The very recent demonstrations that certain peculiar microorganisms of the class of blastomycetes possess the power to produce in animals tumor-like growths in which are cell inclusions, have brought into renewed prominence the question concerning the nature of malignant tumors.

Otto Busse¹ discovered in a case which was regarded clinically as a sarcoma of the tibia, but which the post-mortem examination showed to be a strange case of chronic pyemia with collections of giant cells in the purulent foci, numerous clear and transparent bodies that could be cultivated upon ordinary media. According to their morphology and biology these microorganisms were saccharomyces or yeast fungi, and Busse entitles one of his communications upon this interesting observation "Saccharomycosis Hominis." Following are the principal conclusions in regard to Busse's case of this new disease:

Saccharomycosis hominis is an infectious disease, due to a pathogenic yeast fungus, and characterized by purulent foci in the skin, the bones, the lungs, the kidneys and the spleen. The fungi lie either in the cells, mostly in giant cells ("cell-inclusions"), or outside the cells in the tissue spaces. They are in part naked, in part surrounded by a homogeneous halo as if possessed of a capsule. The majority of the parasites reveal within the capsule, a center with a double contour in which lie one or more glistening bodies. The shape of the organisms is usually circular, the size varying between that of a large nuclear body and that of a liver cell. The saccharomyces can be cultivated in bouillon, gelatin, agar, blood serum, glycerin agar, potato and acid decoction of plums. The cultures usually have a white color, and growth occurs at a temperature varying between 10 and 38 degrees C. In young cultures the organisms present a single contour, only after several days is it possible to recognize a distinct membrane. In plum decoction and grape-sugar bouillon the fungi causes a considerable fermentation, resulting in the production of alcohol and carbonic acid. The microorganism can be transferred to the body of animals, and here they multiply and cause a local, slow suppuration, accompanied with the formation of granulation tissue rich in giant cells and "inclusions," that gradually subsides. In white mice they cause death, and are then present in large numbers in the blood.

A little later Sanfelice² cultivated from the air a certain form of yeast fungus which, when inoculated into animals, caused small ulcers with the formation of new tissue that reminded one of a neoplastic growth very similar to epithelioma. And then Maffucci and Sirleo³ found an organism, similar to the one described by Sanfelice, in a guinea pig that died from marasmus; and which was pathogenic for animals.

From these investigations it is apparent that some of the blastomycetes belong to the parasites of the animal body, and that they are capable of inducing processes of proliferation that in some phase of their development are not unlike some of the malignant tumors. The presence of the saccharomyces within the cells of the proliferating tissue has awakened the hope that we were in a fair way to obtain definite and conclusive evidence that some at least of the various "cell inclusions" described by many workers in carcinoma, and sarcoma also, were really microorganisms as believed to be the case by not a few scientists. Should it be proven that these intracellular formations in carcinoma and sarcoma were forms of fungi, belonging to the blastomycetes, then the sporozoon theory in regard to the etiology of malignant tumors would have to be abandoned,

while the general theory of the parasitic nature of these growths would seem to receive evidence of a very positive nature. It would then appear that all the authors referred to had in reality described and seen genuine parasites, but that they had erred in giving these organisms a place among sporozoa, and that the persistent but fruitless search for spores and sporocytes had indeed been in vain because such structures are not produced by yeast fungi. It would be some consolation at any rate to know that all the time technical skill and energy expended during the last years in the microscopic study of malignant tumors in the search for their cause were, in spite of all the confusion and contradiction that resulted, to be crowned with final success, even though of a different kind than was believed by many of these tireless workers. It is consequently of great interest to read that certain Italian investigators continue to describe the presence of forms of yeast fungi in tumor growths that seemed to them to correspond to certain definite varieties of carcinoma and sarcoma in the sense that these terms are used in medical literature of to-day. Thus Roncali⁴ describes certain parasites in adeno-carcinoma of the ovary. In one case he found them very numerous in the cytoplasm (not the karyoplasm) of cells lying in the stroma of the tumor. In the second case he found these structures in the cell protoplasm and between the connective tissue bundles of the ovarian tumor, which was removed by Durante; also in the metastatic nodules in the omentum which were present. These parasites were identic in form and staining properties with the fungus that Sanfelice used in his experimental studies. It does not appear, however, that Roncali made any culture experiments with the tissues at his disposal, and consequently his observations at most confirm the supposition that the "cell-inclusions" of the recent workers in this field were, in the first place, parasites, and secondly, blastomycetes and not sporozoa. Then Corselli and Frisco⁵ make a preliminary communication of the results of their studies of a case clinically diagnosed as sarcoma of the mesenteric lymph glands, with milky effusion into the peritoneal cavity. The post-mortem examination showed a neoplastic mass composed of new-formed mesenteric lymphatic glands, small ulcers on the mesentery and small intestines, and a large quantity of milky fluid in the peritoneal and pleural cavities. The microscopic examination of this fluid revealed single, or collections in pairs, of oval cellular forms of various sizes. The same formations were obtained in pure cultures from the fluid in the pleural cavities and from the ulcers. Colonies were grown on fucus (seaweed), gelatin and agar. On potato, fruits and decoctions inoculations gave no results. Morphologically and developmentally the parasites presented the same characteristics as the saccharomyces. In the sections from the tumor small cell forms, with granular brownish pigment in their interior were found. The authors believe this pigment to have been formed in the body of the patient. In many instances, distinct evidences of multiplication in the shape of budding processes were also observed.

Animal inoculations were made with the pure cultures and with the milky fluid, and it was found that in guinea pigs, dogs, and rabbits neoplastic proliferation processes occurred in various parts of the body, but especially in the lymph glands; the anatomic structure of, and the arrangement of the parasites in, these animal foci of proliferation were analogous to these in the human mesenteric tumor so that it seems to have been demonstrated that the parasites isolated were the true, specific agents in both instances. The discovery of the fungi described in connection with tumors of the mesenteric glands and chyli-form ascites gives the study of chyli-form ascites a new direction, to say nothing about the relation of this demonstration to the causation of malignant tumors.

In this connection reference may be made to certain peculiar, round or oval bodies described by Flexner,⁶ in a case of multiple lympho-sarcomata. These bodies were free, and apparently entirely foreign to the tissue in which they were found. Flexner thought they were, perhaps, protozoa, but could not say anything definite as to their nature.

In summarizing these recent contributions to the study of the etiology of malignant tumors it can be said that Busse and Corselli and Frisco have succeeded in demonstrating that organisms, belonging to the groups of blastomycetes, may appear in a pathogenic role in man and animals, producing peculiar processes, in some respects very similar to certain forms of malignant tumors: that Sanfelice and Malfucci and Sirleo have demonstrated that this group of microorganisms is pathogenic for animals, initiating tissue proliferations not unlike true neoplasms; and that Roncali makes the claim to have shown histologically that the same parasite was present in two cases of adeno-carcinoma of the ovary. Inasmuch as there is good reason to doubt the true tumor nature of the cases of Busse and of Corselli and Frisco—in fact Busse does not at all claim his case to be one of sarcoma—and inasmuch as Roncali did not cultivate the parasite from his case and reproduce by inoculation into suitable tissue an adeno-carcinoma, the writer is of the opinion that the results of these researches have far greater importance in showing that hitherto unknown infectious processes may be caused by yeast fungi than in establishing the parasitic nature of carcinoma and sarcoma. It may be that instances of infection with yeast fungi, like those described by these authors, have been included under the term sarcoma, the various histologic forms of which may harbor such peculiar processes which Busse and others describe: the word sarcoma may be found to have been applied to a variety of different infectious processes because the structure of its numerous varieties is often not unlike granulation tissue. The convincing proof that carcinoma and the distinct forms of sarcoma are due to blastomycetes, or other parasites, is still lacking; no one has as yet isolated and cultivated the parasite, and reproduced typical tumors by inoculation into susceptible animals. That yeast fungi are pathogenic and may give rise to fatal forms of infection, accompanied with tissue proliferation, and parasitic cell inclusions, are discoveries of far-reaching importance; and continued work in this new direction will undoubtedly yield far more valuable and satisfactory results, even as regards the great problem of the etiology of malignant tumors, than the discouraging efforts to prove the sporozoon theory of their origin by histologic examination only.

Recent Researches on Gout.—The theories as to the causation of gout are still obscure, and the rôle of uric acid in the morbid process is far from being elucidated. All we know is that during the course of the disease regional inflammations are produced with necrotic tendencies, that these inflammatory foci are usually in relation to the deposits of uric acid, but the latter may be missing. A striking example of the latter is found in the necropsy on Professor Cohnheim. For many years this savant had suffered from grave attacks of gout, yet no trace of uric acid deposits were found.

Garrod in his classic work admits there is an increase of uric acid in the blood with diminished elimination in the urine by reason of a functional alteration in the kidney. He supports his opinion by ingenious experiments. When this uric acid has attained a sufficient degree of concentration in the blood it should produce an inflammatory reaction in the tissues with formation of necroses. Ebstein adopts Garrod's ideas in full, save on one point. According to this author the crystallized uric acid is not the cause of the necrosis, the latter is primitive and is a consequence of the diathesis which causes the increase of the uric acid itself. Treatment therefore should

be directed toward the excess of uric acid in the blood. Later on, the methods of analyzing uric acid (Salkowski) showed that the problem was not as simple as had been thought. The elimination of uric acid was sometimes increased, sometimes diminished. Up to the present no analyses have been made of the uric acid in the blood of gouty patients. Nevertheless we find figures similar to those of Garrod in other diseases, for instance in pneumonia. Hence this theory is somewhat unsettled: in fact Van Noorden in his recent work accords it no value whatever. He attributes the principal rôle to the necrosis, and the uric acid found in the inflammatory foci is formed, he says, in these points without any relation with the uric acid of the blood. This uncertainty in theories led Klemperer to make some researches in Leyden's clinic for the purpose of elucidating some points. First of all the quantity of uric acid in the blood of healthy men was to be determined. In no case were appreciable quantities found. Then the quantity of uric acid in the blood of three gouty patients during the attacks was determined, and the same amount found that Garrod indicates (0.05 gr. to 0.1). In one patient the proportion was 0.088, in the second 0.067 and in the third 0.0915. While this shows that the blood during gouty attacks is rich in uric acid, it is not conclusive, for Klemperer found 0.985 gr. in a case of leukemia and 0.0165 gr. and 0.0685 in two cases of nephritis. On the other hand, uranalysis in the second and third patients gave 0.423 and 0.710 of acid, so we can not conclude there was a diminution in the elimination. Finally, a great number of uranalyses were made in gouty patients between and during the attacks, but there was no concordance between the access and the quantity of uric acid. Hence the analysis of this acid in the urine is of no value in the diagnosis. As to the production of necroses by stasis of the uric acid in the tissues, it is necessary to first establish the quantity of the acid soluble in the blood, for if this is precipitated from the blood it is because the latter is saturated. Blood serum from three healthy individuals was digested with uric acid at 37°. It was found that 100 cubic centimeters of the blood had dissolved in one case 0.166 gr. in another 0.171, and in the third 0.143 of the acid. The same experiment repeated with blood from the three gouty individuals taken during the paroxysms gave 0.14, 0.126, and 0.18 (the most grave attack). It seems from these researches that the blood of gouty patients even during the attacks may still dissolve large quantities of the acid, and we can not admit there is a supersaturation and consecutive precipitation during the paroxysms.

It might be claimed that the blood is less alkaline during the attack and the uric acid is precipitated. Experiments made on the three patients gave 28, 31 and 33 volumes per cent. of carbonic acid, figures but little lower than the normal (36 volumes per cent.). Hence this hypothesis also fails us. What, then, is the origin of the necrotic process? For answer we can only invoke analogies. Thus we may cite observations on saturnine intoxication. Garrod, and later on Leyden, showed that in cases of lead poisoning there are foci of necrotic inflammation very similar to those in the gouty. We are now prepared to admit that certain toxic substances circulating for a long time in the blood cause necroses in which uric acid is deposited. Alcohol acts in the same manner as lead. If the toxic agent of gout is still unknown to us it is certain at least that it oxidizes very readily, and that anything increasing its oxidation diminishes the attacks. Treatment, then, should be directed toward increasing oxidation. For this purpose we may recommend moderate alimentation, appropriate muscular exercise and abundance of drinks. *Les Nouveaux Remèdes*. 1895, No. 15.

Hoppe-Seyler.—In a consideration of the life of Hoppe-Seyler it is brought to notice that we owe to him much of our knowledge of the inter-relations of chemistry and physiology, from

⁶ Johns Hopkins Hospital Reports, Vol. III, p. 171, 1893.

the fundamental principles of the one to the highest problems of the other. It was his aim to secure for physiologic chemistry a position as an independent branch of science. At an early period he was an assistant with Virchow. He filled the chair of applied chemistry at Tübingen eleven years. Then, in 1872, at the reestablishment of the University of Strassburg, he was selected above many to increase its scientific reputation, and there he remained to the end. In 1884 an independent institute was built for him. His published works are exceptionally numerous: at first in anatomy and medicine, as studies on cartilage, bone, teeth, the theory of percussion. He soon turned to medical chemistry and wrote on chondrin, serous transudates, the influence of cane sugar on digestion, etc. Then came a paper on the effect of carbonic acid on the blood, in which the chemie proof of carbonic acid poisoning was first shown in the dead body. This was the beginning of a long series of researches on the blood. In 1862 he first described the spectrum of hemoglobin. To him is due the proof that oxyhemoglobin does not accomplish the physiologic oxidation in the blood of albumin, fat and sugar, as had been often assumed, but that it is to be regarded as a means of carrying oxygen into the tissues. He showed how to obtain blood crystals pure. He recognized that oxygen gave to hemoglobin its power to resist decomposition and the pancreatic juice, and proved the elaboration of oxygen in green plants. There is hardly a branch of physiologic chemistry that has not been advanced by Hoppe-Seyler. He bestowed careful work on the composition of bile, on enamel, pus, milk, urine, lecithin, nuclein, the great group of albuminous bodies which he arranged in a plain and natural system. So in the chemistry of plants there is his work on chlorophyll, on the influence of algae on the gases of fermentation. His researches on fermentation and putrefaction are extensive. With all these manifold works, he yet held in view those powerful forces which have so influenced the earth's crust. So we find investigations on the formation of anhydrite and dolomite, on flow of gas in coal strata, on the optical properties of oxid of manganese, the production of light by motion of atoms. These show us on what a broad foundation his knowledge and investigations were developed.

His *Physiologic Chemistry*, begun in 1877 and finished in 1881, is a work of great importance and had the task of embodying in a connected manner all known facts. Much earlier appeared his "Handbook of Physiological and Pathologico-chemical Analysis," which rested in great part on methods original with Hoppe-Seyler. This extensively-used book is now in its sixth edition by Hoppe-Seyler and Thierfelder. The lack of a special journal for physiologic chemistry led him, in 1877, to establish the *Zeitschrift für Physiologische Chemie*, which has a well-assured existence. Naturally pupils came from all over the world to work with him: a great number of publications arose under his direction and bore witness to the enthusiasm which reigned in his laboratory. Preparations to celebrate his next birthday were brought to an end by the news of his death. A great gap remains where this man of science stood. *Wiener Klinische Rundschau*, August 25, 1895.

The Prevention of Cholera; Dr. Haffkine's Work in India. The very able address given by Dr. Haffkine at the Examination Hall of the Royal College of Physicians and Surgeons, explained the results of the work which he has done during the past two years and a half in India in carrying out the practice of his method of vaccination as a preventive of cholera in India. Dr. Haffkine's work is of the highest scientific value and promises to confer a great boon on the Indian empire. It has been carried out under circumstances of the most remarkable self sacrifice and devotion to the interests of humanity and of science. He has given many of the best years of his life to this research, and has with unwearying industry and transparent sincerity worked out in India all the details which

can test the value of this new gift to science to life-saving purposes, without fee or reward other than his own conscience, his love to humanity and his scientific devotion. Dr. Haffkine has with steady diligence and unquestionable enthusiasm braved every danger, and endured the extremes of climate and of unhealthy seasons. He has listened to the appeals from every direction regardless of personal risk and unmindful of his own health, which has suffered greatly. He returns to Europe greatly debilitated by the continuous trials of his arduous labors. In India he earned the respect and affection of all with whom he came in contact. His unaffected simplicity of character, his undeviating search for the truth regardless of any other object than that of the largest possible application and the most rigorous tests of his method, have won for him universal esteem. It is fitting that his first great public reception should have been in this country, for it is in the Indian empire that his discovery and his invention will find its largest field of usefulness, and while the boon which he has conferred on humanity is one which all the world must recognize, and by which all will be benefited indirectly, even where not directly, still it is especially in the Indian endemic home of cholera that the application of this method will find a most useful field. It may be hoped that with the larger views on sanitation which the Indian government is now adopting and carrying out, and with the universal recognition in India and the unspeakable importance of recognizing the water-borne theory of the causation of cholera, the necessity for the application of Dr. Haffkine's method will become narrowed within diminishing limits.

Dr. Haffkine concluded his address by a touching, eloquent, and deeply-felt tribute to the memory of his illustrious master, Pasteur, from whom he derived his inspiration, and who gave, it should be remembered, the most generous financial help, as well as his scientific aid and countenance, to this great enterprise of Dr. Haffkine. The adoption of the Pasteur filter throughout India, where it is now being extensively introduced, will in its own way tend probably almost as largely to prevent the development of cholera as Dr. Haffkine's vaccination will limit its extension within the areas of its prevalence. Thus Pasteur's name will be doubly connected with the crusade against this terrible plague, which usually slays hundreds of thousands in the Indian empire, and thus extends its ravages from time to time to European countries. The Pasteur filter and Haffkine-Pasteur vaccinations will go hand in hand in rendering this great service to humanity. The tribute which Dr. Haffkine paid to the memory of his great master comes at a timely moment, and every one who reads his luminous and convincing address will feel that his concluding words are not the least interesting part of it. We trust that the Indian Government may see its way to some just and adequate recognition of the unstinting services which Dr. Haffkine has rendered to the great Indian dominions, and that his unexampled devotion and self-sacrifice will not pass without due official recognition.

British Medical Journal, December 21.

Can Leprosy be Stamped Out? The London letter writer for the *American Practitioner and News* speaks hopefully of a proposed new treatment of leprosy, by the artificial induction of erysipelas upon the leprosy members of the patient. He credits the suggestion to Dr. W. Impey, Medical Superintendent of the leper settlement at Robben Island, Table Bay, who is now in England on a six months' leave of absence. During his vacation he intends to visit the various leper establishments in Norway, Russia, Turkey, and the south of France, in order to see the method of treatment, and if possible to experiment with a view of testing what he believes to be an effectual cure for the disease in its earlier stages. Dr. Impey has found that at Robben Island, where there are six hundred lepers, that when a patient is attacked with any inflammatory skin disease, such as measles, erysipelas, or smallpox, the part affected is invariably cured of leprosy, and the patient either entirely recovers from leprosy or his life is indefinitely prolonged beyond the normal eight years. Dr. Impey contends that erysipelas should be induced within three or four years if a patient be attacked, and by this means he thinks leprosy may eventually be stamped out.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, JANUARY 11, 1896.

DECIDUOMA MALIGNUM.

The history of the malignant tumors following normal labor, abortion, hydatidiform mole, or extra-uterine pregnancy and composed of decidual or placental elements, begins with SÆNGER's¹ report to the Leipzig Obstetrical Society, July 16, 1888, of "two unusual cases of abortion," one of which occurred in a 23-year-old woman, who aborted in the eighth week and died seven months later, with four large, soft, spongy, reddish tumors in the uterine wall and metastases of the same character in the lungs, diaphragm, tenth rib and right iliac fossa. The microscopic examination showed a hemorrhagic structure with cells similar to those found in the decidua; he named the tumor "deciduoma malignum." In 1893 SÆNGER published a more extensive monograph² in which he collected all that was known of this kind of tumor and compared his case with those which had been described since his first report.

The year after SÆNGER's first report PFEIFER described a similar case from Chiari's institute in Prague, and without knowing of SÆNGER's previous work, likewise proposed to call it a deciduoma malignum. During the last five or six years the number of such cases has increased rapidly; the majority of the cases have been described by German authors, a few by French and Italian observers, but in this country and in England a well authenticated case had not been reported until WILLIAMS,³ of Baltimore, very recently described what he called a typical case. It is also true that BACON, of Chicago, described a case from Chiari's institute in the *American Journal of Obstetrics*, vol. XXXI, No. 5, 1895, so that now when

the attention of American workers has been directed to the subject it may be expected that more cases of deciduoma will be recognized and studied in this country than heretofore.

References to this tumor are not found in many of the recent American or English text-books. As WILLIAMS⁴ says, it is apparent to any one who has read the various descriptions of the authors, that the growths which have been described as malignant deciduomata, or by more or less cognate terms, differ very materially among themselves, and an idea as to the various interpretations is well gained by enumerating some of the designations which have been applied to them. SÆNGER at first called his case deciduoma malignum, and later sarcoma uteri deciduo-cellulare. GOTTSCHALK⁵ first called his case sarcoma chorion-deciduo-cellulare, later sarcoma chorii; FRÆNKEL,⁶ carcinoma arising from the chorionic epithelium; KLEBS,⁷ placental papilloma, etc. But in spite of the differences in the onkologic and histogenetic interpretation of the growths, these so variously designated tumors form a distinct clinical group. They all follow closely upon some form of pregnancy, either abortion, normal labor, hydatidiform mole or extra-uterine pregnancy, and quickly lead to the death of the patient with the rapid formation of metastases, especially in the lungs and the vagina. In order to group all these tumors under some distinctive designation, which will enable one to speak of them from a clinical standpoint, without at the same time wishing to express any definite connection as regards their intimate origin and structure, WILLIAMS⁸ proposes that the term deciduoma malignum be retained as best suited for this purpose at the present time. After thoroughly sifting the accumulated material WILLIAMS finds that at least twenty-six cases have already been described which from a clinical standpoint should undoubtedly be classed among the malignant deciduomata. The etiology of this tumor is unknown. The most striking etiologic relation is its close connection with pregnancy of some form. Of the twenty-six cases referred to eleven followed hydatidiform moles, six full-term pregnancies, five abortions, one a tubal pregnancy and in three cases the form of pregnancy preceding the tumor is not stated. The majority of deciduomata maligna occur in young women. One case occurred before the 17th year, twelve cases between 20 and 30, five between 30 and 40, four between 40 and 50, one case occurred at 55 and in three the age was not stated. The most constant symptoms is uterine hemorrhage following pregnancy in some form; it may appear immediately after the completion of labor or abortion or be delayed until some months later. This hemorrhage occurs at intervals, and is

⁶ Arch. f. Gyn., XLVIII, 1895.

⁷ Die Allgem. Path., II Theil, 690, 1889. ⁸ Loc. cit.

usually of a gushing kind. The uterine cavity is more or less completely filled by a soft reddish placental-like mass. After removal the mass returns rapidly and invades the uterine wall. Hemorrhage may be absent. The rapid formation of metastases and early death are characteristic. The secondary tumors develop most frequently in the lungs and the vagina, pulmonary growths being observed in almost every fatal case; vaginal metastases were observed in 58 per cent. of the fatal cases. Death usually occurs within six months of the first appearance of symptoms. To one whose attention has been directed to this class of cases, the occurrence of hemorrhage soon after normal labor, abortion or hydatidiform mole, which recurs after curetting and becomes associated with symptoms of pulmonary involvement and perhaps vaginal tumors, would point strongly to a probable clinical diagnosis of malignant deciduoma. In the early stages diagnosis can only be made by means of the microscope. Here the presence of decidual cells or masses of syncytium making their way between the muscle cells would enable one to make a positive diagnosis, as has already been done by GOTTSCHALK,⁹ MENGE¹⁰ and others. The treatment that would hold out any hopes whatsoever for permanent recovery is total extirpation of the uterus with its appendages after an early diagnosis. Thus far seven cases have been operated on in this manner; three of these died from recurrence of the growth, six seven and twelve months respectively after the removal of the uterus. The other four cases recovered from the operation, but sufficient time has not yet elapsed to allow any judgment of its ultimate success. The onkologic relations and histogenesis of these tumors that have been referred to in the foregoing as representing a distinct clinical group to which the name of deciduoma malignum may not unfittingly be applied, are somewhat difficult to understand and have been variously interpreted by the writers. This fact, it has been pointed out, is strikingly illustrated by the extensive variety of descriptive terms introduced from time to time to express the opinions of the authors as regards the structure and origin of the tumors they had occasion to study.

These tumors arise in a locality in which fetal and maternal tissues come in close contact and in which epithelial and mesoblastic cells are closely blended and consequently the questions which constantly presented themselves have been those relating to the possible origin of the tumor, whether fetal or maternal, and to the histologic structure of the neoplasm, whether carcinoma, sarcoma or mixed. These questions have been quite clearly solved in some instances, in others positive conclusions could not be reached. A very brief review of some of the more typical cases will undoubtedly tend to show that deciduoma ma-

lignum includes tumors of different structure and histogenetic origin. SÆNGER'S, PFEIFER'S, CHIARI'S and BACON'S cases all showed that the solid parts of the tumor as well as the wall of the blood spaces were made up of typical decidual cells lying in a connective tissue stroma, so that one can be quite safe in concluding that these were all instances of sarcoma uteri deciduo-cellulare. In the cases described by MEYER,¹¹ KLEBS,¹² GOTTSCHALK,¹³ FRÆNKEL,¹⁴ MARCHAND,¹⁵ WILLIAMS¹⁶ and others the tumors were composed largely of blood, certain irregular protoplasmic masses that are easily traced to the chorionic epithelium or syncytium, and also certain individual cells concerning the origin of which more or less uncertainty of opinion prevails. The weight of opinion of to-day is in favor of regarding the syncytial covering of the villi as coming from the uterine or tubal epithelium, consequently of maternal origin, and the form of deciduoma which consists essentially of syncytial masses, as in FRÆNKEL'S case, would be, in accordance with this statement or view, a carcinoma of maternal origin (carcinoma syncytiale, choriocarcinoma). The distinct, individual cells which are found in some at least of these syncytial carcinomas have received varying interpretations. Thus MARCHAND,¹⁷ whose recent studies concerning the so-called "decidual" tumors following normal labor, abortion, hydatidiform mole and extra-uterine pregnancy, have attracted so much attention, traces the component elements of many "decidual" tumors to, 1, the syncytium, *i. e.*, the uterine epithelial layer of the chorion from which giant cell-like and irregular protoplasmic masses come, and 2, to the cellular layer of LANGHAN'S, *i. e.*, the ectodermal fetal chorionic epithelium. MARCHAND says that the peculiar symbiosis which normally characterizes these elements likewise explains their combination in the tumor formation; this peculiarity extends to the entire arrangement of the two forms of tissue and to the formation of blood spaces within the syncytium and the lack of other vessels. While MARCHAND'S views in regard to the very important part played by the syncytium has been favorably received as a rule, his teachings as to the origin of the smaller cells found in these tumors have not met with such universal approval. Thus WILLIAMS is inclined to think that the cells which MARCHAND considers derived from the fetal ectoderm, may after all only represent cross sections through syncytial masses; and KOSSMANN¹⁸ regards MARCHAND'S assumption in regard to the chorionic ectoderm as untenable, because the new growth extends outward away from the fetus instead of into the fetus as one would expect. KOSSMANN traces the small distinct cells back to the syncytium and re-

gards them as having been formed in syncytial masses in which the cell boundaries have reappeared. GOTTSCHALK¹⁹ can not abandon the idea that the tumor described by him as sarcoma of the chorionic villi is in part, at least, a sarcoma and consequently he insists that tumor proliferation may also occur in the stroma of the chorionic villi, as well as in the epithelium. The majority of the writers doubt the correctness of GOTTSCHALK's conclusions.

A case described by MENGE²⁰ seems to represent the third possible anatomic and histogenetic variety of deciduoma malignum, namely a mixed sarcoma and carcinoma. In his tumor there are apparently decidual cells and masses from the syncytium, so that the tumor is derived from both the connective tissue and the epithelial elements of the decidua, if the maternal origin of the latter be accepted. We may summarize the present status of opinion concerning the onkologic relations of the anatomic varieties of deciduoma malignum as follows:

1. There is a sarcoma uteri deciduo-cellulare, cases of which have been described by SÆNGER, PFEIFER, CHIARI, BACON and others.

2. There is a syncytial or chorionic carcinoma of the uterus produced by malignant proliferation in the uterine epithelial layer of chorion (FRÆNKEL, WILLIAMS, KOSSMAN) and in the fetal ectoderm (MARCHAND).

3. There may be a mixed sarcoma and carcinoma (carcino-sarcoma) made up of decidual cells and syncytium (MENGE).

4. The tendency of opinion is to regard all these tumors as of maternal origin, but it must be remembered that definite conclusions on this point can not well be reached as long as the embryologists are not of one mind as to the fetal or maternal nature of the tissues in question.

FIREPROOF STAIRS FOR HOSPITALS AND FACILITIES.

The *Sanitary Record* has the following compilation from German journals concerning the researches and experimentation now progressing in that country for the prevention of life loss by fire, where faulty stairs exist in factories, hospitals, hotels and lodging-houses.

Since the terrible fire at Aachen on Dec. 1, 1893, when a number of lives were lost through the stairs becoming early impassable from smoke and flame, the question of the best means of avoiding such a catastrophe, whether in factories, in industrial block dwellings, or in public institutions, has engaged the attention of many architects in Germany. K. Henrici recommends that all stairs should be completely shut off from the workshops and rooms by absolutely

fireproof walls; that they should be connected with these by open corridors, balconies or bridges easily reached, that the windows of the stairs be so placed as not to be exposed to smoke or flame issuing from the building. With these precautions, and direct access to the open air below it does not much matter, in his opinion, whether the stairs are at the side or in the middle of the building. Oppermann maintains, on the other hand, that perfect safety can be secured only by having the stairs in a tower completely isolated from the body of the building, communication being effected solely by means of bridges. But unprotected iron structures are not to be trusted, since, if exposed to the flames, they become rapidly heated. He would give the preference to arches of brick work without any iron, but remarks that the weight and stress of the arch might be greatly reduced by the use of highly porous Lochstein, while the iron girders necessary for the support of bridges, balconies and galleries, should be well protected by non-conducting and fireproof materials, of which slag wool, enclosed in a shell of one or other of fireproof cements, is certainly the best. The Lochstein mentioned by Oppermann is an artificial stone, a sort of spongy concrete, manufactured at one or two places on the Rhine. For the steps themselves iron would be the very worst material; these, if not of brick or stone, should be of hard, slow-burning wood, as oak or teak, in solid sleeper-like blocks.

THE LAY SUPERINTENDENT AGAIN.

The chief medical officer of the Cook County Lunatic Asylum has just been under trial before the County Civil Service Board for insubordination to the lay head of the institution. It appears that he made arrangements for a post-mortem of a patient whose death he could not otherwise certify without consulting his superior.

It is a strange condition of affairs when a medical chief of a medical institution can not decide medical questions without the interference of a non-medical official and must be tried for insubordination if he attempts so to do. Not long since the profession in this country was profoundly stirred in behalf of a naval surgeon who was court-martialed for not obeying an order of his superior in a matter that his medical conscience would not permit him to act as he was commanded. He, however, was simply a subordinate in a war ship—a fighting machine—where according to naval discipline the combatant officer must be supreme; it was not in a hospital, the main and only function of which is medical, and where every thing in its administration has a medical bearing that can only be properly estimated by an educated physician. To make the cases parallel, the doctor should have court-martialed the admiral for not consulting him in some matter of naval tactics or navi-

¹⁹ Zeitschr. f. Geb. u. Gyn., XXXIII, II Heft. p. 349, 1895.
²⁰ Loc. cit.

gation, as here the man with simply a business training and no medical qualifications whatever assumes to dictate in matters beyond his proper scope and to discipline the one who should in the proper order of things be his chief, for not responding to his dictation.

In an article entitled "Politics and the Insane," in the *North American Review* of last October, Dr. HENRY S. WILLIAMS scores severely the municipal charities of several of the chief cities of our country, and especially those connected with the care and treatment of the insane. Whatever grounds he may have had for his strictures on the others, there is much in the past record of the Cook County institution that support his statements, and the present incident will not advance its reputation as a notable example of what a hospital for the insane ought to be.

The fact is, the medical profession too supinely accepts the situation when so-called business men take upon themselves functions that ought properly to be deputed to qualified physicians. The much talked-of superior business ability of laymen in charge of medical institutions is a fiction; very ordinary business ability is really required, and it should be easily found in subordinates under the direction of one qualified to see the medical bearings of all matters of management and administration. It is not super-eminent "business" ability nearly as much as common honesty that is required in the lay administration of a public medical charity, and experience in the past has demonstrated that this essential can not be too carefully looked after. By the same test of experience it is easily shown that the most satisfactorily conducted asylums or hospitals are always those under a medical head and where the professional rather than the business ideal is supreme.

We should be glad to see the same general interest taken by the medical profession in this as in the Kershner case, and to have a general expression of the condemnation of lay management of purely medical matters and lay dictation in questions that can properly be only decided by qualified physicians. There is no lack of competent medical men, but they are not likely to want to assume positions where their professional feelings will be outraged and their proper functions usurped by those who are incapable of appreciating the one and incompetent for the other. There has been and is too much of this sort of thing, and we are too often impudently asked "what are we going to do about it?" It is time that there should be some expression of medical opinion in regard to it.

The reinstatement of Dr. McGREW was an act of justice, but according to report, the order of restoration was accompanied with a "caution" to be "more careful in observance of the rules." This is equivalent to saying, "not guilty, but don't do it again." The principle involved, the complaint of the medical profession, is thus not recognized.

CORRESPONDENCE.

Typhoid Fever

AS SEEN AND TREATED FORTY YEARS AGO COMPARED WITH THE TREATMENT OF THE SAME DISEASE AT THE PRESENT TIME.

To the Editor: When attending the lectures of Prof. J. K. Mitchell, in the Jefferson, 1853, I remember of his theory that typhoid fever and other fevers were caused by fungi. He wrote a book on the subject. Should any member of the class of 1853 read these lines they will bear me out in these statements. He asked me in the green room what was the duty of a physician when called to a patient with typhoid fever. I gave him in reply the verbatim statement he gave in his lectures, that he should act in the capacity of a pilot or steersman on a boat to steer the craft clear of dangerous breakers. This was found to be a difficult thing to do. We found the tongue heavily coated, dry and cracked, lesion of the glands of the small and large intestines, tympanites, hemorrhage, and sometimes perforation of the bowels with other alarming symptoms. I will not occupy your time reading the treatment of typhoid fever forty years ago, for it was too unsatisfactory with too great mortality. Have we any more light on the subject? Are we treating it more satisfactorily and with more favorable results? I say yes. Thanks to Dr. Woodbridge for his abortive treatment of typhoid fever. I have treated eighteen cases this fall precisely as he directed in papers read by him at San Francisco, Baltimore, and other society meetings, without a single loss. Where the disease was not complicated I had none of those dangerous breaker symptoms. Instead moist tongues, no tympanites, no tenderness, no lesions, no hemorrhage nor perforation of bowels. Why such difference in symptoms and results? Because we sterilize the alimentary canal, preventing parasites from locating and doing mischief therein. If called in time I have no more fear of fatal results in typhoid fever with no complications than I have in bilious or intermittent fever. It used to be a terror to patients to tell them they had typhoid fever: not so now. A case in point: I discharged a young lady yesterday, Miss C. F., of one of the first families in the city. Her father was much alarmed when he found I told her she had typhoid fever. He asked me why I told her. I said because she is intelligent and has confidence in her physician. I told her that her temperature was $104\frac{3}{4}$, that I was using Dr. Woodbridge's abortive treatment of the fever, and that in two weeks her temperature would be $98\frac{1}{2}$. On the fourteenth day she asked to see the thermometer; said she, "98 $\frac{1}{2}$ exactly." She further said I am now not afraid of typhoid fever. I told her she could commence solid food gradually and that she had no further need of my services. This case is a fair sample of those treated by me this fall. I am not writing this to flatter Dr. Woodbridge, but to encourage my professional brethren who have not tried it, to do so at once. The question has been frequently asked me by my professional brethren how I had succeeded. I say up to and beyond my expectation. I find it much easier to handle typhoid fever now than forty years ago. Dr. Mitchell was coming in the right direction with his fungi, but he slept with his fathers ere he had formed the acquaintance of Drs. Pasteur, Koch, and others, or had seen or heard of microbes or bacteria. A number of years ago I found that the temperature in typhoid fever could be controlled and the fever shortened about two weeks with salicylic acid and carbonate of ammonia in solution. I was not aware at the time that I was treating the disease scientifically by sterilizing the alimentary canal. I now see and know that is the secret of Dr. Woodbridge's Abortive Treatment of Typhoid Fever. It is no fad or secret quack remedy, but a scientific and successful treatment. None of us are too old to learn and none of us should be too prejudiced to adopt any treatment that has been shown to relieve suffering and save life.

E. J. MCCOLLUM, M.D.

Some Curious Proper Names.

CHICAGO AS AN ANATOMIC AND PHYSIOLOGIC ENTITY.

CHICAGO, Jan. 1896.

To the Editor:—Some time ago while looking through the 1894 Chicago Directory for the residence of a slow-paying patient we became impressed with the remarkable number of anatomic and physiologic terms made use of by the Human family to distinguish each other, and the idea occurred to us of Making Man in a Shape, Size, Weight and Motion similar to ours from the parts thus obtained. It will be observed that it required no inventive Genius, for the process was purely synthetic. With a Model before us and not being limited to Dust or Mudd, we took a Bone, and then finding any number of Bones, we decided upon having a Full compliment of Ribbe's rather than leave a Ribout. Having thus obtained a Skeleton our next step was to add Joints and Marrow. Looking about us we were Fortunate in finding Brain, Lung, Heart, Liver, Bile, Gall, Stomach, Bowel or Gut and Kidney. Having placed them Each in their Proper Place, we discover that we are slightly handicapped in being Able only to obtain a Vein for the Blood and Kyle. Nothing daunted, however, we Seize what Musil, Flesh and Hyde we can Lay Hold upon and Start at the Pate. Having Given our Friend a a Noble Brow and a Broadhead we hesitate whether he should have Hair or Remain Bald. Finding but one Ey is a cause of Grief, yet with Earee's sufficient there is consolation.

Next Comes the Nose, no restriction as to Style, Hence we make it Roman, adding the Jaus, Chin and Cheek, next the Mouthe and Lips, not forgetting the Tongue or Gums. We can find no teeth, but rejoice in being thus permitted to dispose of a possible Toothaker. So Much for the Head. Now for the Body or Trunk. With a Back, Bussom, Bottom, Belle and Navel in position we make our image High-Breasted, supplying the Arms and adding a Hand with its Palm, Thumb, Finger, Knuckles and Nails it makes a respectable looking Fist. Turning our attention to the extremities which we Lack, we Have in Stock Hip, Legg, Knees, Shin, Shank, Ankel and Foot; also some Corns. As to sex we have our Choice, having Both Penas and Overy. As to Agee, a Baby Boy or Girl, or it may Grow into estate as a Youngman or Maiden, Gentleman or Lady, Damsel or Dame. This Person may be Lean, Lank, Long and Lively, or Stubby, Short, Thick, Fat and Slick. Having fashioned it we set it upright and observe it Wants a Soul with which we endow it. We call it a Gent. Give him a Beard and Clothes and now having Breathed easier, we Hear and See him Speak, Stammer and Read. After a Cough he begins to Chat, Telling us of a Cramp after which he felt a Little Pewki, this was followed by a Severe Chill, during which he thought he would Freeze, but soon came a Fever and Sweat.

He tells of a Boil which was some time in Healing and was very Sore, but is now disposed to Heal, but it will leave a Scarr. He is given a Dose of Pils and we leave him in Peace and Comfort, expecting them to effect a Cure. If he again becomes Ill and should Croak, giving up the Gost under the care of another Doctor, we have a Coffin in which to Bury him and also a Grave, and can thus obtain his Korps and have him Cutup into the pieces from which he was Made.

All the words capitalized I found in the 1894 Chicago Directory.

G. H. S.

An Alleged "Health University."

MILWAUKEE, WIS., Dec. 27, 1895.

To the Editor:—The inclosed advertisement appears daily in the *Milwaukee Sentinel*. Is anything known of this institution in Chicago? Sincerely Yours, JNO. MADDIX.

PERSONAL.—How to become lawful physicians. Course by mail. Illinois Health University, Chicago.

ANSWER.—The Illinois attorney-general has filed in the cir-

cuit court an information against the "Illinois Health University" of Chicago. The charges are that the "University" confers the M.D. degree without personal examination of applicants from the States of Ohio, Indiana, Michigan, Wisconsin, Idaho and Kansas, and such other States as do not require the diploma of a reputable medical college, or an examination before a State board of health. The court is informed that the school is conducted on the "correspondence" basis.

PUBLIC HEALTH.

Beriberi from Punta Arenas.—The American bark, *Herbert Black*, left Punta Arenas, Chili, on July 20, with several of the crew slightly ill. All hands except the captain and three others were down with beriberi early in November. Barbadoes was then the nearest port, and the captain laid his course thither. He arrived on November 22. Nine men were sent to a hospital, where four of them died. The *Black* shipped a new crew and sailed on December 1, arriving at New York harbor December 21. The skipper says that on a trip from Punta Arenas two years ago nearly all of his crew became ill of beriberi. He says that the crews of nearly all sailing vessels taking cargo at Punta Arenas suffer more or less from this disease.

Indiana Board of Health. The Indiana State board of health January 3 announced stringent rules in regard to the introduction of infectious diseases into the State, and the notice is accompanied by the statement that the rules will be rigidly enforced. They provide that any common carrier or person bringing any sick person or persons suspected of being sick with smallpox, diphtheria, membranous croup, scarlet fever, or any communicable disease, shall be liable to certain penalties and the corporations or persons so offending shall also be liable for the charges incident to the care of such sick persons by the local health authorities. It is made the duty of the conductor of a train or the master of a steamboat to notify by telegram the secretary of the board of health of the presence of such sick person on his train or vessel, in order that suitable provision may be made for preventing the spread of the disease, and all trains and vessels coming to Indiana from any point where communicable diseases obtain shall be subject to inspection by the local health officer and the charges of such inspection shall be a valid claim against the corporation. The shipment of any one dying of membranous croup shall not be granted, and no permit shall be issued for the shipment of a body having died of "heart failure" unless the cause of heart failure is stated.

Unstable Sterilized Milk. The workers at the Pasteur Institute are still engaged in the study of the ferments of milk. According to *Public Health*, for November, in a recent number of the *Annales de l'Institut Pasteur*, Dr. E. Duclaux makes an exhaustive examination of the objections against the use of sterilized milk made by Flugge. The latter has stated that the liquid often sold in flask as sterilized milk contains a liquid which has become materially changed. In order to understand how this change is brought about, it is necessary to review the action of ferments on casein. It is well known that ordinarily the formation of lactic acid from sugar precedes the coagulation of casein in milk by a special ferment. Pasteur first showed that milk may coagulate under the influence of ferments in a neutral medium. The ferments of casein secrete a second diastase antagonistic to the first, which reduces the coagulum formed by the former. Then the coagulum again becomes liquid, and the passing coagulum may have been overlooked; this transformation although hidden is very great. In milk, casein, we know, is not in solution, but in suspension, forming with the serum a stable emulsion, of which the elements are fine enough to pass through filterpaper, but too gross

to pass through porcelain. When the second diastase has acted, the albuminoid matter is completely dissolved. Furthermore, a portion has been decomposed into the intermediary products which lead on to leucin, etc. The hygienic question in connection with milk is the determination of the microbes causing it to produce infantile diarrhea. It is notorious that such diarrhea is diminished, or even prevented, by the use of boiled milk. Is it the ferments of lactose, or those of casein which are inimical? Dr. Dueleaux thinks it is the former among other reasons, because experience shows that it suffices to render milk harmless (so far as diarrhea is concerned) for ingestion to Pasteurize it, *i.e.* to heat it 70 to 75 degrees, a temperature at which the lactic ferments are killed, but which the ferments of casein and bacilli resist.

Compulsory Cleanliness for the Homeless in New York.—At a meeting of the new Department of Public Charities, New York city, amid the whirl of Christmas-tide, a salary or so was raised, and a few more nurses allowed. Also Commissioner Faure in a matter-of-fact way favored the establishment of a float alongside the pier at East Twenty-sixth Street, as a tramps' lodging house. Here he proposes to house all the tramps of the city, thus relieving the police station houses. The motto of the place he said, would be "No bath, no bed." Each day the lodgers of the night before would be taken to the Island, and they would be kept there three days until their cases could be investigated. Then the regular vagrants would be sent to the workhouse, and the deserving ones sent to their friends. It will be hard indeed, in these days of popular rights, to tell whether or not the lay press might not stigmatize the project as a gross outrage, familiar as they have become with the buncombe speeches of damage-suit lawyers and of a bench drawn from the same element. As for our Western tramp, not so much the product of a motley over-dense population, he is more cleanly and being more submissive to the advances of civilization has long since, in the words of Emerson "Converted an experiment into a sacrament." As we take it, a bath to some temperaments must be much worse than "sawing wood and saying nothing," although the people so far have seemed to view the matter with indifference. The organ of the reformers should no longer separate the bath-master from the Ambulance-Surgeon whose blunders come to us from the cities of the far East. The tramp, as a rule, is a mild mannered man attempting to anticipate his millenium, whose virtues should exempt him from the hardships of soap and water. To sum up the situation we must deplore the advent of a new party since the Constitution impliedly guarantees the right of every man to go to bed unwashed, and if needs be, with his boots on. Besides too, we can not refrain from depriving the drama of so picturesque a character as a tramp, even though he begs more beds than he really needs. In fact the insidious encroachments of tyranny must be resisted, even though it comes to us in the trappings of sanitary reform. No citizen is obliged to submit to a clean skin any more than to a free vaccination.

Health Reports. The following health reports have been received in the office of the Supervising Surgeon-General Marine-Hospital Service:

SMALLPOX—UNITED STATES.

Ohio: Martin's Ferry, Dec. 1 to 28, 139 cases, 3 deaths.
Michigan: Detroit, Dec. 21 to 28, smallpox reported.
Tennessee: Memphis, Dec. 14 to 31, 22 cases.

SMALLPOX—FOREIGN.

Batoum, Dec. 3 to 10, 1 death.
Cairo, Nov. 26 to Dec. 2, 1 death.
Havana, Dec. 19 to 26, 1 death.
Glasgow, Dec. 14 to 21, 3 deaths.
Madras, Nov. 16 to 22, 1 death.
Madrid, Dec. 10 to 17, 9 deaths.
Montevideo, Nov. 23 to 30, 9 cases.
Naples, Dec. 11 to 18, 4 cases, 4 deaths.
Nogales, Mex., Dec. 21 to 28, 1 death.

Odessa, Dec. 7 to 14, 10 cases, 1 death.
Rotterdam, Dec. 14 to 21, 4 cases.
St. Petersburg, Dec. 7 to 14, 12 cases, 4 deaths.
Tuxpan, Dec. 14 to 21, 1 death.

CHOLERA—FOREIGN.

Bombay, Nov. 27 to Dec. 10, 6 deaths.
Calcutta, Nov. 16 to 30, 118 deaths.
St. Petersburg, Dec. 7 to 14, 78 cases, 43 deaths.
Yokohama, Dec. 19 to 26, 5 cases, 2 deaths.

YELLOW FEVER—FOREIGN.

Havana, Dec. 19 to 26, 5 cases, 2 deaths.
Sagua la Grande, Dec. 14 to 21, 23 cases, 3 deaths.
San Juan de Puerto Rico, Nov. 29 to Dec. 20, 63 cases, 23 deaths.

BOOK NOTICES.

An Atlas of Ophthalmoscopy, With an Introduction to the Use of the Ophthalmoscope. By DR. O. HAAB, Professor of Ophthalmology, University of Zurich. Translated and edited by ERNEST CLARKE, M.D., B.S. (Lond.), Fellow of the Royal College of Surgeons, etc. New York: William Wood & Co. 1895.

This is the first of a series of five medical atlases William Wood & Co. propose to publish and to sell by subscription at \$15 for the set. If the present volume can be taken as a standard for the whole series, the subscribers will get five excellent and useful works at an astonishingly low price.

This atlas contains in sixty-four colored plates ninety-eight ophthalmoscopic pictures with descriptive text, and a good short introductory lecture on the ophthalmoscope and its uses. All these pictures were carefully sketched from nature by an expert ophthalmoscopist (Professor Haab) and skillfully reproduced in excellent chromo-lithography.

The collection comprises seven pictures of the various appearances of the normal fundus, eight pictures of congenital malformations, fourteen pictures of diseases of the optic nerve, fifty pictures of the diseases of the retina, and nineteen of the diseases of the choroid. No word paintings, however artistic, could give the student of ophthalmoscopy an adequate idea of the appearance of the eye-ground in health and disease as vividly and accurately as these beautiful drawings.

That the book is not a large cumbersome volume—as the word "atlas" might suggest but of the very convenient small octavo size, and that the descriptive text for each plate is printed on the page facing it, are two points showing the excellent judgment of the publishers of what is needed to make a book convenient for ready use and reference.

Spectacles and Eyeglasses, their Forms, Mounting and Adjustment. By R. J. PHILLIPS, M.D., Adjunct Professor of Diseases of the Eye, Philadelphia Polyclinic and College of Graduates in Medicine, etc. Second edition, revised. Philadelphia: P. Blakiston, Son & Co. 1895.

This little book gives in its hundred pages a wealth of information which is not found in our text-books on ophthalmology, but which is indispensable to every oculist and physician who wants to become an expert in the fitting of spectacles and eyeglasses. And what makes the book particularly commendable is its simple, comprehensive language, free from the scientific jargon which renders many ophthalmologic books so distasteful and indigestible to students.

The New York County Medical Association. We have received a copy of the annual handbook or register of this large society for the year 1895-6. It is a well-printed and well-bound book of 176 pages, and contains a large quantum of useful professional information, beside the regular personal lists. It is illustrated by a fairly good portrait of the late Dr. William Detmold, the first President, in 1884, of the now great local organization of over one thousand in membership who have not bowed the knee to the Bial of the agnostic banner of the old State Society of New York.

Literary Announcements.

The *Popular Science Monthly*, now in its thirtieth year, has added new departments on Invention and Electricity, and the number of pages have been doubled. These signs of prosperity are indeed rather gratifying to all friends of popular education.

IN OUR notice of the volume of *Medico-Chirurgical Transactions* of London, on page 824 of our last volume, it was stated that most of these papers had been published elsewhere. This was an error, as the papers printed in these Transactions are not allowed to be elsewhere printed. Gentlemen desiring to read these papers will therefore have to purchase the Transactions.

ASSOCIATION NEWS.

Celebration of the Centennial Anniversary of the Discovery of the Protective Power of Vaccine Virus by Dr. Edward Jenner, 1796.

The committee appointed by the AMERICAN MEDICAL ASSOCIATION and the auxiliary committee appointed by the American Public Health Association to prepare a proper program for this centennial, propose the following order of proceedings designed to occupy one entire day of the annual meeting of the AMERICAN MEDICAL ASSOCIATION to be held in Atlanta, Ga., May 5 to 8, 1896:

THURSDAY, THIRD DAY OF THE MEETING.

Morning Session.—Address on "The Character of Dr. Edward Jenner and the History of his Discovery of the Value of Vaccination," by Dr. N. S. Davis, Chicago, followed by discussion on the history and status of vaccination in this country.

Afternoon Session.—Paper on "The Scientific Researches Relating to the Specific Infectious Agent of Smallpox, and the Production of Artificial Immunity in this Disease," by Dr. George M. Sternberg, Surgeon-General U. S. A. Also paper on "The Propagation, Preservation and Use of Vaccine Virus," by Dr. Francis C. Martin, Boston, Mass. Discussion, especially on the scientific principles involved in the papers.

Evening Session.—Paper on "The Statistic Evidences of the Value of Vaccination to the Human Race," by Dr. Eugene Foster, Augusta, Ga. Discussion as far as time will permit.

COMMITTEES.

OF AMERICAN MEDICAL ASSOCIATION: Drs. N. S. Davis, Chicago, Ill.; J. M. Toner, Washington, D. C.; H. D. Didama, Syracuse, N. Y.; J. F. Hibberd, Richmond, Ind.; J. S. Billings, Philadelphia, Pa.

OF American Public Health Association: Drs. T. George Simons, Charleston, S. C.; C. A. Lindsley, New Haven, Conn.; Angel Contreras, Pueblo, Mexico; J. M. Toner, Washington, D. C.; N. S. Davis, Chicago, Ill.

Jan. 4, 1896.

SOCIETY NEWS.

XII Congress International de Medecine.—Sous l'auguste patronage de Son Altesse Impériale le Grand Duc Serge Alexandrovitch. Moscou, 19-26 août 1897. Comité Exécutif: Président, Prof. I. F. Klein; Vice-Président, Prof. A. J. Kojewnikow; Trésorier, Prof. N. F. Filatow; Secrétaire Général, Prof. F. F. Erismann; Secrétaires, Prof. P. I. Diakonow, Prof. W. A. Tikhomirow, Prof. I. I. Neyding; Membres, Prof. A. A. Ostrooumow, Prof. S. S. Korsakow.

COMMUNICATION.—In accordance with the august approval of His Imperial Majesty the Emperor of Russia the XII International Medical Congress will be held in Moscow between the 19 and 26 of August (new style) in the year 1897, under the Patronage of His Imperial Highness the Grand Duke Serge

Alexandrovitch. Further details about the organization of the Congress will be published at as early a date as possible.

Secretary General, PROF. F. ERISMAN, M.D.

We shall publish the rules next week.

NECROLOGY.

JAMES E. REEVES, M.D., of Chattanooga, Tenn., Jan. 4. He was born in Amisville, Rappahannock County, Va., in 1829. He was one of the founders of the American Public Health Association, and was president of that body in 1885. He removed from Wheeling, W. Va., to Chattanooga some years since. As a sanitary authority he was able and conservative. He was distinguished as a microscopist, and before the days of bacteriology he was a skilled manipulator; his mounted specimens were beautiful and much sought after. He was an inventor of many useful methods and recently wrote a small book, reviewed in this JOURNAL, which contained much valuable information on this subject. He was a valiant and uncompromising upholder of the code of ethics of the AMERICAN MEDICAL ASSOCIATION, and while not long a member of the Board of Trustees, his influence was always thrown strongly in favor of measures for the exclusion of objectionable advertisements from the columns of the JOURNAL. He was an active and useful member, and his death is deeply regretted by the remaining members of the Board.

FRANK PUTNAM BUFFUM, M.D., of Chicago, January 6.—**J. M. Taylor, M.D.**, of Corinth, Miss., December 28. He was born in Jackson County, Ga., in 1826. He was twice chosen President of the Mississippi State Medical Association, and served for many years as a member of the State Board of Health.—**Thomas S. Powell, M.D.**, of Atlanta, Ga., December 30, aged 70. He was born in Brunswick County, Virginia, in the year 1826. In 1864, shortly after the war, he went to Georgia, locating in Sparta, where he commenced the practice of his profession. In 1878, Dr. Powell moved to Atlanta and has been identified with the practice of medicine ever since. He was noted for his great charity and his kindly feeling toward the poor. Dr. Powell's greatest professional accomplishment was the founding of the Southern Medical College, of which he was President up to his death.—**William Compton, M.D.**, of Lancaster, Pa., December 13, aged 70.—**V. R. Bridges, M.D.**, of Mattoon, Ill., December 20.—**E. J. Alter, M.D.**, of Aspinwall, Pa., December 15, aged 32.—**A. C. Peters, M.D.**, of Iowa City, Ia., December 18, aged 34.—**E. Francisco, M.D.**, of Parsons, Kan., December 18, aged 84.—**M. B. Folwell, M.D.**, of Buffalo, N. Y., December 10, aged 54.

MISCELLANY.

Dr. E. L. B. Godfrey, of Camden, has been elected Secretary of the State Board of Medical Examiners of New Jersey, in place of Dr. Wm. Perry Watson, of Jersey City, who resigned to accept the position of Medical Supervisor of the Prudential Insurance Company at Newark.

A Poorhouse and Insane Asylum Burned. The Jefferson County poorhouse and the asylum for the insane near Fairfield, Iowa, were both destroyed by fire January 8. There were over thirty inmates in the two buildings but all were rescued without loss of life. The loss is estimated at \$10,000. Insurance \$4,000.

Appointments. Dr. George Dock, at present Professor of Practice of Medicine and Pathology in the University of Michigan, Ann Arbor, has been elected Professor of Pathology and Bacteriology in the Jefferson Medical College.

Professor Daniel R. Brower of Chicago, has been appointed a member of the Illinois State Board of Health, *vice* Dr. George Thilo resigned.

A Condensed Code Dating from the 14th Century.—Guy de Chauliac, French surgeon, author and teacher, was the chaplain and physician-in-chief for Urban V and two other popes of Avignon. He was educated at the universities of Bologna and Montpellier and a long while a practitioner at Lyons. He was born about the year 1300. He inculcated the following embryo code of ethics:

"Bold when sure. Cautious in danger. Kind to the weak and sick. Friendly with fellow-workers. Constant in duty. Not greedy of gain."

College Library.—The library of the College of Physicians and Surgeons of Chicago has received 1,378 bound volumes since the first request was made for donations of books six months ago. These books have all been accessioned and nearly all catalogued and thus made available to students. There are a great many pamphlets, unbound books and unbound periodicals not included in this list. The more important American and a few European medical serials are represented by complete sets. This library is open only half the day at present, and yet the number of readers is increasing steadily. The librarian would be glad to receive further donations and solicits correspondence with that end in view. The duplicates will be exchanged with any library in need of them.

Blind-fold Practice.—Sir Edwin Arnold, in his introductory address at St. Thomas' Hospital, London, on "Medicine; its past and future," after a reference to the customs of that benighted land which absolutely forbids the high caste Indian ladies availing themselves of male European skill says. "I was dining once in Jeyhore at the table of Surgeon-Major Hendley, the able and trusted friend of the Maharajah, when a message came that the chief Queen had been taken ill and begged the advice of the British hakim. He went and on return told us that although for seventeen years a familiar visitor of the palace, and the private advisor of the Rajpoot Prince, he had been obliged to suffer his head to be enveloped in a silken bag, and so equipped had been led into the zenana, where he had felt the pulse of her Highness, and had examined her with the stethoscope without seeing an atom more of his patient than a glimpse of one jewelled slipper through the strings of the bag." This would seem to open up a good field for blind practitioners of the male sex, as well as for female doctors, and many of the latter have made a marked and rapid success of it, by locating in those Oriental cities where males are not wanted in the zenanas.

A Long-Haired Colored Woman. In *Leslie's Weekly* for January 2, there appears an account, with an illustration of the "only living long-haired negress," named Nancy Garrison, a resident of Holly Springs, Miss. She is a true negro, black and with kinky hair; and her age is 48 years. When she was thirty years old a change took place in her hair, subsequent to an attack of fever. "Until 1878, after the yellow fever epidemic, there was nothing remarkable about Nancy, but during the scourge she had the fever and came near dying. It was months before she was able to leave her house. Immediately after her convalescence her short, kinky hair began to grow rapidly: in a year's time it grew from three inches to three feet in length, thickening as it grew. A few years later and the crispy mass of hair fell below her knees. About this time a wonderful change of color took place: the jetty locks turned white as snow and remained so until two years ago: since then the hair has gradually turned to its natural blackness. It continues to grow and now measures eleven feet. Prominent physicians have examined her head and hair and are disposed to think that the spell of fever produced the unnatural growth. Nancy is a living curiosity, visited by hundreds who handle her massive braids before they believe the truth."

The Hospital Hotel. The pay wards of the hospitals of New York city are getting to be more freely used by the well-to-do

classes, especially by the males, and still more especially by those who need to undergo surgical treatment. According to *Polyclinic*, even millionaires, having their own luxurious private homes, find in the hospital surroundings that are more favorable for a prompt and sure recovery than they can get elsewhere. Not only is this true where surgery is involved, but in many cases where medical treatment alone is necessary. Cases of typhoid fever are well represented among many other ailments, and occasionally, though not often, a consumptive, even, will decide to end his days amid the peace and quiet of the "hospital hotel." Wealthy patients, who may choose and pay for anything that their fancy dictates, are beginning to appreciate very decidedly the advantages of becoming private patients in any of our best hospitals.

Trained nurses may be secured now at short notice at home it is true (two are necessary, alternately relieving each other) but aside from this, both physician and patient have discovered that during a case of dangerous illness, or in recovering after an operation, the perfect quiet and routine of the hospital régime are more desirable than being surrounded by home and friends or any amount of luxury. The benefit, it appears, lies chiefly in being removed from the every-day, familiar scenes, where every object is apt to remind the invalid of some duty undone or some mountain ahead. It is a species of "rest cure." There seems to be a dreamy, drowsy atmosphere about a hospital patient's existence which is very soothing to invalid nerves. They have a vague idea, to be sure, that it is all very tedious, and that they are not keeping up with the procession properly at all, but it is only a shadowy impression. Then there is every possible patent contrivance at hand in a hospital, and there is always the house surgeon to be summoned at any minute, should the patient so desire.

The private rooms vary in price, ranging from \$25 to \$60 a week, including board and nursing. An hour's time where a great surgeon is employed, is apt to mean a few extra hundred, possibly an extra thousand or more. The rooms are plainly but tastefully furnished, draperies of any kind being rigidly excluded. Draperies encourage microbes. Aside from the suffering involved, there are many pleasant memories connected with a few week's stay. There comes a time when the pains and aches are a thing of the past, and then the patient relapses into that delightful, dreamy, *dolce far niente* existence called getting one's strength back. There is a feeling of abject dependence upon the white-capped nurse: no returning nightmare of duties undone is suggested in this peaceful spot, and really the only effort demanded of one is to select a small list of delicacies for the next meal.

The nurses are, almost without exception, well bred, well educated specimens of womanhood. This profession requires considerable tact and although beauty is not absolutely required, there are many of the hospital nurses who have rather more than their share. They are highly appreciated, as a rule, and many enduring attachments are formed between patient and nurse.

Essentials to Recovery from Druggist for Giving Injurious Medicine.

Several fundamental principles of importance are established by the Supreme Court of Iowa in the case of Rabe vs. Sommerbeck, where it, on May 21, 1895, reversed a judgment for the plaintiff. This was an action brought against a druggist for damages resulting from alleged negligence in giving the plaintiff injurious medicine. First of all, the court holds that in an action of this character the plaintiff must aver and prove a want of negligence on his part contributing to the injury complained of. It says that this, in the application of the rule, is much like the case of Baird vs. Morford (29 Iowa, 531), where the negligence complained of was in reducing a dislocated shoulder joint, and where it was distinctly laid down that "a party claiming to recover for the negligent or unskillful acts of another must show him to be in the wrong, and also prove, i

issue thereon is made, that no negligence of his own caused the injury." The opportunities for contributory negligence in the two cases are much the same. At the particular time of treatment, in each case, there seems to be but slight opportunity for such negligence, but still there is some. In both cases, after the treatment, there is a demand for reasonable care, and a want of it may become contributory negligence. In the second place, the court holds that the jury should have been instructed: "If you find from the evidence that croton oil was by defendant administered to plaintiff in dangerous quantity, as is alleged, then you will consider whether or not it was the proximate cause of plaintiff's sickness and injury, as alleged; and if you find that it was not the proximate cause thereof, or if the plaintiff was sick at the time of administering the croton oil, if any was administered, and the same did not increase the sickness or pain, or the duration thereof, then you should find for the defendant." The plaintiff was sick when he went for the medicine, and whether or not it was the drug administered that caused the sickness and suffering that followed, the court explains, was a very important fact in the case. True, the instructions which were given only permitted a recovery if the drug administered caused the injury; yet there was nothing in them to call the minds of the jury to the importance of distinguishing between these two facts, either of which might have been the cause of the suffering and the condition complained of. The court also says that the symptoms of the plaintiff after taking the drug are proper in determining its character, and also that, with the proper foundation, expert evidence is competent for that purpose. If the facts having support in the evidence are stated hypothetically to the expert, it is proper for him to state the conclusion whether or not croton oil, or any drug which is a subject of injury, would produce such symptoms or results.

Practical Notes.

The Gouty Nature of Persistent Hiccough.—The *Lancet* for October 26 has some remarks on the above subject by Dr. John Roche. Rheumatic gout is a frequent cause in those cases where no lesion of the cerebrum exists. Salicin in thirty-grain doses three times a day will effect a cure in four days or less, if my surmise be correct. If the case should be due to centric nervous system derangement producing an erythematous condition of the nasal, pharyngeal and gastric mucous tracts of an intermittent nature small doses of arsenic, nux vomica and iron three times a day, with milk and lime water night and morning, will be the remedy. He has known the case of a gentleman affected with sneezing which suddenly attacked him after intervals of a few weeks, and lasted day and night continually. He has known a case where hiccough, sneezing and laryngeal asthma were periodic visitants. Arsenic and tonics relieved the first; salicin cured the second.

Trephining for Chronic Hydrocephalus; Recovery.—A case of Mr. William Thelwall Thomas is reported in the *Lancet*, of a young man, aged 19 years, who was subjected to the operation of trephining about six months previous. The history of the case showed a very severe and progressive headache, generally occipital, for eighteen months, extreme giddiness and ataxia, with falling to the right side. There were nystagmus, diplopia, paralysis of the right superior oblique, and marked double optic neuritis. The circumference of the head was 25 inches. The right cerebellar fossa was opened and the tense, non-pulsating dura mater bulged; this was opened and then the brain bulged. By exploring with the finger no tumor could be made out, but the space under the cerebellum was closed by a membrane; this was easily broken through with the finger, and a quantity of clear fluid liberated. The medulla and floor of the fourth ventricle were distinctly felt. The bone was not replaced. The headache soon disappeared, and the man quickly regained all his faculties and is now apparently quite well, six months having elapsed since the operation. Dr. Glynn, when he suggested the performance of this operation to Mr. Thomas, thought the case was one of cerebellar tumor. The patient was nearly blind at the time of the operation. It

was remarkable that it should not only have been followed by temporary relief, but also by permanent recovery. It was possible that a posterior meningitis had been followed by adhesions between the membranes in the neighborhood of the fourth ventricle, and had in this manner caused chronic hydrocephalus.

On the Irrigation of Pus-Joints. In the *Bulletin* of the Johns Hopkins Hospital, the treatment of pyarthrosis is reported upon by Dr. Finney, the operation being that of a free incision and an abundant irrigation with a bichlorid solution. One of his cases was a young man aged 17, who was admitted to the hospital August 8, under Dr. Bloodgood's care. Early in June he had a pain in his left knee, which was followed by some swelling and tenderness and slight pain on motion. He was unable to walk with comfort for about a week; after that it gave no further trouble. This was clearly a case of synovitis. Two days before admission to the hospital, while playing baseball, he fell and injured the same knee. This was followed by rapid swelling, great pain and tenderness. On admission his temperature was 104 degrees; pulse, 120; face flushed. The left knee was contracted almost to a right angle; it was most comfortable in this position, resting on the outer side. The joint was much swollen, with the patella floating. There was considerable fixation, due to the muscular spasm; some redness about the joint, and it was extremely tender. The joint was first aspirated and a cloudy fluid withdrawn. Later it was incised in the manner about to be described. This method is the point of especial interest to us. It was suggested by Dr. Halsted because of the uniformly unsatisfactory results of the old method, which was by inspiration or incision, followed always by the insertion of drainage tubes. The final result of that operation was, in the most favorable cases, a stiff knee. In many there was a resection of the joint later, and in a large proportion of cases an amputation of the leg. The operation done in this case was, after applying a tourniquet to the thigh, to make a long incision into the joint on either side of the patella, through which the joint was irrigated with several gallons of 1 to 1000 bichlorid solution. Then the tourniquet was removed, the wounds covered with protective and treated in the ordinary way. There is little to be seen now except two parallel granulating wounds. He has been recently anesthetized and the fibrous adhesions which had formed broken up. Dr. Welch discussed the bacterial side of the case briefly. He said that this procedure of opening and irrigating pus joints is interesting in reference to the question of disinfecting surfaces of the body. There has been a good deal of experimental work done by Schimmelbusch and others, with the object of ascertaining whether it is possible to disinfect an infected surface or to prevent infection. Dr. Williams has made some observations here with reference to that point in cases of streptococcus infection of the endometrium. He has shown that the micro-organisms are so deep that one can not possibly think of the disinfectant reaching them. While there appears to be no doubt of the superior efficacy of irrigation with disinfectant solutions, as opposed to simple salt solutions, the grounds for this are not altogether apparent, as experiment show that these disinfectants do not actually kill all of the organisms even on exposed surfaces, and do not reach those in the depth of the tissues. Of course these remarks relate only to the possible theories or explanations of the process of cure and are not a criticism of the efficacy of the procedure, which is determined only by experience.

Paracentesis of the Spinal Sheath. According to the London *Lancet*, Quinke, of Kiel, is among the first, if not the first, to practice puncture of the spinal sheath in cases of cerebro-spinal meningitis, whether tuberculous in origin or not. This expedient has not been much practiced elsewhere, and in some cases has not been followed by permanent results. It is obvious that if it is to be of use in tuberculous meningitis the case must be one in which no other region or organ is the seat of miliary tubercle, and that may explain the fact of failure to insure recovery even after a marked improvement as regards

the cerebral symptoms, such as disappearance of coma has followed the lumbar puncture and drainage. He affixes a manometer to the trocar and thus measures the degree of pressure within the canal. Failure to secure a flow of fluid is to be attributed to imperfect performance of the puncture. *e. g.*, the passage of the needle between the nerve-roots outside the sheath, or the presence of thick pus which will not flow through a too fine needle. He is convinced of the therapeutic value of the plan especially in rapidly developing forms of acute serous and sero-purulent meningitis. The assistants at Dr. Quinke's clinic are now engaged in the preparation of a detailed report of his cases.

Dr. Von Ziemssen is quoted as to having said that he had seen ample confirmation of the reports as to the diagnostic and therapeutic value of the lumbar puncture since its introduction by Prof. Quinke. He himself had injected a weak solution of iodine into the canal by this means. He did not use a trocar, but Dieulafoy's needle. Sometimes the patient, shrinking at the moment of puncture, approximated the vertebrae and thus hindered the entrance of the needle, and he thought that anesthetics should be given in the case of adults. No reaction followed, and in some cases examined after death no trace of the puncture could be seen. Furbinger has reported to the Medical Society of Berlin that he has tapped the vertebral sheath in eighty-six cases, making the puncture over one hundred times. The puncture is made in the second, third or fourth intervertebral space in the lumbar part of the spine: the patient sitting up rather than lying on the side. The author states that anesthetics are unnecessary, and that aspiration is more painful than the puncture itself. The amount of fluid withdrawn varies from a few to 110 c.c. Out of thirty-seven cases of tubercular meningitis, of which twenty-seven were verified by autopsy, the tubercle bacillus was not found in seven cases. Of this 80 per cent. in which the diagnosis was established, there was a number of cases which could not be diagnosticated from the clinical symptoms. The therapeutic results were unsatisfactory. In three cases of serous meningitis there was a transient amelioration of the symptoms. Dr. A. Frankel holds that the operation is harmless if done correctly. The puncture should be made about on the plane of the junction of the superior and middle thirds of a spinous process, about two fingers' breadth from the median line. After passing through the skin the needle should be directed slightly upward and inward, and it then enters the canal without difficulty. He failed to find tubercle bacilli in meningitis, notably those in which the arachnoid membrane was affected, and therefore the absence of tubercle is no proof that the disease does not exist. In the *Boston Medical and Surgical Journal* for December 12, Dr. T. M. Rotch reports a case observed by him at the Boston Children's Hospital, in a female aged 2 years, who had marked cerebral symptoms. "We punctured the spinal canal, using for the purpose a needle from an antitoxin syringe, and withdrew six cubic centimeters of a clear fluid which looked like distilled water. No tubercle bacilli were found in this fluid and only rarely a cell of any kind. The albumin was quantitated and found to be less than one-twentieth of 1 per cent. Cultures made from the fluid were negative. The child showed marked stupor at the time, and when aroused acted as if blind. Examination of the eyes showed them to be normal. There was an acute, double, sero-purulent otitis media: but although paracentesis was performed and the ears carefully treated, the symptoms persisted. These were moderate temperature of an irregular type; urine negative; persistent diarrhea, five to six movement daily, of a green color and more fluid than normal. Immediately after tapping the canal the child became restless, throwing herself about the bed, clutching at her hair and giving vent to short cries. The patient recovered and the diagnosis was never made. From the examination of the fluid withdrawn from the canal it was evident that there was no inflammatory exudation in it, which was of some value in diagnosis. Although it is

not at all uncommon in infants and young children to have cerebral symptoms in cases of otitis media rather than local ones, still, after paracentesis has been performed it is usual for the symptoms to subside very quickly. In this case they persisted for more than a week afterward. If a moderate diarrhea can account for the symptoms in any way, whether toxic or not, it is a unique experience. The child had been ill for ten days, as nearly as we can find out, and remained for three weeks in much the same condition in the hospital. Recovery gradually occurred.

Society Notes.

THE MINNEHAHA MEDICAL SOCIETY, Sioux Falls, S. D., have considered a proposition from the medical society at Sioux City for the organization of a tri-State Medical association made up of the members of the fraternity in Northwestern Iowa, Southwestern Minnesota and Southeastern South Dakota. It is the plan to hold meetings of the proposed association quarterly for the discussion of questions of interest to the members.

Hospital Notes.

THE BOARD of Cook County Commissioners held the first meeting of the year January 6. Various reports were received and referred to the proper committees. That for the poor-house showed the number of inmates on Dec. 1, 1895, to be 1,535, the number admitted during the month 400, and the number of births 2, making a total of 1,937. The discharged numbered 283 and the deaths 31, leaving an attendance at date of 1,623. The report of the Cook County Hospital showed the number of patients during the last month had averaged 801. Dr. E. C. Fortner was appointed County Physician for the year ending December, 1896.

Louisville Notes.

SOCIETIES. The Clinical Society will be entertained January 11 by Dr. J. M. Krim, the title of his essay being "The Use of Forceps in Difficult Labor." Dr. Louis Frand will entertain the Surgical Society on the 13th, the title of his paper being "Strangulated Umbilical Hernia, with Report of Case." Dr. W. R. Blue entertained the Falls City Medical Society on January 1, reading a paper upon "Electricity in Dermatology and Genito-Urinary Diseases." The Louisville Academy of Medicine met in their rooms in the College of Pharmacy building on the 6th, Dr. Hugh N. Lavell reading the essay on "Chloroform Anesthesia."

DEATH REPORT.—The report of Health Officer White for the month ending January 3, shows a total of 293 deaths. The total number of deaths during the same period last year was 335. During the month pneumonia and consumption each caused forty-one deaths, eighteen died from organic heart disease, fourteen from typhoid fever, and eleven from bronchitis. There were thirty-two stillbirths.

COLLEGES. The Hospital College of Medicine began its regular session on January 2 with a large medical and dental class. The Kentucky School of Medicine began on January 3, with 210 matriculates. There is every indication of a prosperous year, both schools requiring three years' study for graduation. The 1897 term will inaugurate the four years course.

St. Louis Notes.

WEEKLY HEALTH REPORT. Total number of deaths reported during the week ending December 28, 200, compared with 167 for the preceding week, and 135 for the corresponding period of 1891. Total number of births reported during the week, 231. For the week ending January 4, total number of deaths 180, compared with 146 for the corresponding period of 1895. Births reported, 310.

Contagious diseases reported during the week ending December 28: Diphtheria 94 cases, 13 deaths; typhoid fever 6 cases, 3 deaths; measles 16 cases; scarlatina 9 cases; whooping cough 14 cases, 1 death. For the week ending January 4: Diphtheria 83 cases, 12 deaths; croup 7 cases, 1 death; typhoid fever 9 cases, 2 deaths; cerebro-spinal fever 1 death; measles 12 cases.

THE ST. LOUIS MEDICAL SOCIETY held its fifty-ninth annual meeting on the evening of December 28. Reports of the officers and committees of the year closed were submitted. The election of President, for the ensuing year resulted in the choice of Dr. W. G. Moore. At the meeting January 4, Dr. Moore assumed his office, and, after a short address announced the following committees: Ethics—Drs. F. D. Mooney, L. P. Pohlmann and Hall G. Tupper. Elections—Drs. J. P. Heinrich, John H. Duncan and John B. Shapleigh. Publication and Debate—Drs. G. M. Phillips, Chas. L. Wilson and F. C. Ameiss. Executive—Drs. Keating Bauduy, Given Campbell and C. M. Nicholson. Library—Drs. Ludwig Bremer, Wm. Johnson and S. Pollack.

DR. L. CH. BOISLINIERE, the venerable physician, lies critically ill at his home. Hopes are entertained of his recovery.

THE CASE OF J. M. BEECHER.—On December 23, J. M. Beecher was brought before the probate court for an investigation of his mental condition. The point of peculiar interest was the circumstance that he had been confined in the city asylum more than two years as a patient, and had made every effort possible under the circumstances to prove his sanity and his right to liberty. He is possessed by the delusion that he is the head of a great detective agency and called to hunt down all enemies of society. Aside from his delusions he is acute and logical in all his mental activities, and it was deemed best by the authorities to have his actual status determined beyond all cavil. The remarkable feature of the case is that the jury had no hesitancy in declaring the patient to be insane, though as compared with the paranoiac, Dr. Duestrow, his mental irresponsibility is much less evident.

THE ANNUAL MEETING OF THE STATE BOARD OF HEALTH was held at Jefferson City, January 2. The routine business of the board was attended to. The matter of midwives in St. Louis advertising as physicians was discussed and a rule adopted prohibiting such signs from being publicly displayed. The following officers were elected for the ensuing year: Dr. F. J. Lutz, St. Louis, president; Dr. T. H. Hudson, Kansas City, vice-president; Dr. Willis P. King, Kansas City, secretary. The board adjourned to meet in St. Louis Monday, January 6, when the question of the necessary qualifications of students who enter medical colleges will be determined.

Detroit Notes.

THE DETROIT MEDICAL AND LIBRARY ASSOCIATION was entertained Monday, December 30, by Dr. Geo. Henry Fox of New York, who gave a lecture illustrated by stereoscopic views. The Doctor exhibited a great many original slides, the most of them being syphilitic lesions, others being smallpox, psoriasis, eczema, acne, lupus and lichen planus. The first was of a primary lesion, syphilis on the lower lip. It was characteristic and showed the lymphatic involvement along the angle of the jaw. The next few slides were of secondary syphilis, then came one of erythematous syphilid which the speaker dwelt upon for a few moments and brought out the point that the case was one of recurrent: then a slide or two of papular syphilid. The Doctor took occasion to remark that there were no cases of syphilis that were not vesicular, and syphilitic lesions do not itch. Here was shown a very nice case of alopecia of the early second stage, then several slides of smallpox and chickenpox; these were in the umbilicated stage and showed the depressions very nicely. The next was a case of psoriasis. The Doctor then remarked that in syphilis we have considerable infiltration of the skin, but in psoriasis the opposite is the rule. His case of lichen planus was a beautiful case; the color and the papules showed very nicely. His cases of acne were very characteristic, being one of punctate, one of sebaceous and one of molluscum: and the remark was made that of 100 men that were taken at random and their chests and backs examined, 80 per cent. of them would be found afflicted with this trouble. In those of scabies and phthieriasis the diagnosis was made in the latter case by the parallel lines made with the finger nails of the patient seeking relief,

and the lecturer said that the latter disease was much more contagious than the former. In returning to syphilis, he said, we have four varieties, squamous, papulosus, pustulosus and macular. As to skin lesions in syphilis the further away from the stage of incubation that the eruption appears the more likely are we to find a grouping of the lesions. A beautiful picture was shown of ring-worm, upon the outer edges of which was what appeared to be syphilitic lesion. This was confirmed by examining the patient's mouth when the lecturer made his ultimate diagnosis. A case presenting Hutchinson's teeth was shown with accompanying secondary eruption: the next a late syphilis accompanied with papillomata of the vulva. The lenticular papular ulcer on the palm after the secondary lesion has disappeared is a positive means of diagnosing syphilis. The eruption in syphilis is generally unilateral, the further away from the primary lesion, especially after the first year. A case of tubercular or nodular syphilis was then shown. Then several cases of lupus were shown. In making the diagnosis between this disease and syphilis age should be taken into consideration as lupus begins generally before one has been exposed to syphilitic contagion, and lupus is a slow growing lesion, while syphilis in marked contrast spreads rapidly. Lupus, the speaker said, was not an incurable disease, but one that required a long time, months even years to cure, and its ravages knew no bounds. In showing some cases of eczema of the leg it was noted how syphilis affected the upper part of the leg and eczema the lower part. In showing his case of psoriasis he commented upon the fact that in this disease ulceration does not occur and that the healing generally is from the center. Here was shown a view of a hand, in the center of the palm of which were seen scaly patches. This, the Doctor said, was also characteristic of syphilitic lesions. In speaking of the treatment of syphilis, he said there was no disease so amenable to treatment, that the remedies were mercury and potassium iodid, and that he had found no better way of giving them than by the mouth, as he does not like inunctions. As illustrative proof of this, he showed a tubercular syphilid in which the tubercles were upon the upper lip and the end of nose, the eight or nine being as large as the last joint of one's thumb. This case had had the usual heroic treatment. He had taken the case, quit all treatment, insisted upon the patient's taking a good walk every day, regulated the diet, and was gratified in the short space of a fortnight by seeing marked improvement in his patient. Dr. Fox further said that he knew that his listeners understood that all cases of this kind need good food and air, but he brought this forward to emphasize the importance of diet and exercise.

HEALTH OFFICE REPORT for week ending Jan. 4, 1896. Deaths under 5 years 27, total 64. Births, male 55, female 54, total 109. Contagious diseases: Diphtheria, last report 34, new cases 16, recovered 22, died 5, now sick 23. Scarlet fever: Last report 22, new cases 7, recovered 9, died none, now sick 20. Smallpox: Last report 2, new cases 1, recovered 1, died none, now sick 2. Measles: Last report none, new cases 2, recovered none, died none, now sick 2.

Washington Notes.

WEEKLY REPORT OF THE HEALTH OFFICER. The report of the Health Officer for the week ended December 28 shows the health of the city during the past week continued to average above the normal. The deaths numbered 107, and the annual death-rate was 20.2 per thousand inhabitants as against 22.6 in the corresponding period of last year. The principal features of the week's health history were the gradual rise in the prevalence of heart troubles from which there were eleven fatal cases, and from lung maladies causing thirty-four deaths. There were five deaths from typhoid fever as compared with four therefrom in the corresponding week of last December. Malarial diseases present no phase of importance, and with the exception of four deaths from diphtheria, the dangerous contagious ailments were in abeyance. The mortality among children under five years of age was forty-one, of which thirty were under one year old. The mortality among this class was mainly pneumonia and cognate lung maladies in connection with brain disorders, which are accountable for twenty-nine of these cases. A general review of the pathologic conditions justifies the con-

clusion drawn from the death list, that the health of the district is above the average.

BIOLOGICAL SOCIETY'S OFFICERS.—The Biological Society has elected the following officers for 1896: President, Surgeon-General George M. Sternberg, U. S. A.; Vice-Presidents, Richard Rathbun, C. D. Walcott, L. O. Howard, B. E. Fernow; Recording Secretary, M. B. Waite; Corresponding Secretary, F. A. Lucas; Treasurer, F. H. Knowlton; Members of Council, F. W. True, C. W. Stiles, W. H. Ashmead, F. V. Coville, and C. L. Pollard.

SELECT COMMITTEES OF THE SENATE APPOINTED. The following are some of the Select Committees of the Senate appointed by the presiding officers:

Epidemic Diseases. Vest, chairman; Harris, Irby, Jones (Nevada), Gallinger, Quay and Butler.

To Investigate the Condition of the Potomac River Front of Washington—George, chairman; Martin, Blanchard, Frye, Sherman and Perkins.

To Establish University of the United States—Kyle, chairman; Sherman, Hawley, Frye, Nelson, Jones (Arkansas), Turpie, Walthall and Mitchell (Wisconsin).

THE WOMAN'S CLINIC.—The quarterly meeting of the Woman's Clinic was held on the 4th inst., at the office of the Society. Reports of officers were read and other important business transacted; the report shows the work of the hospital to have largely increased.

CENTRAL DISPENSARY AND EMERGENCY HOSPITAL. At the regular monthly meeting of the staff held on the 4th inst., the following report of its work done during the past month was read. Number of new cases 832; visits 2,250; emergency cases 197; redressings 358; ambulatory cases 42; prescriptions compounded 3,508; deaths 2; post-mortem examinations 2. A great deal of the work done was for the relief of serious accidents and included abdominal and brain surgery.

TO PRACTICE IN NEW ORLEANS.—Dr. Meyer Herman of this city, formerly one of the assistants at the Emergency Hospital, has gone to New Orleans, La., to begin practice there. Dr. Herman left a large and lucrative practice and a host of friends.

PHYSICIAN VS. PATIENT. Dr. H. L. E. Johnson has entered suit in the Circuit Court here to recover fees amounting to \$250 for professional services.

A PATIENT THREATENS DAMAGE SUIT. A patient of a prominent physician here is on the verge of entering a suit for \$10,000 damages. The patient claims to have been injured permanently by the performance of an injudicious abdominal section. It is understood that a compromise is to be effected if possible.

THE POST-GRADUATE SCHOOL OF MEDICINE OF THE DISTRICT.

At a recent meeting of the directors of the school the recommendations of the Curriculum Committee to arrange the subjects and assign the professors as follows was adopted: Gynecology, Dr. H. L. E. Johnson; Surgery, Orthopedics, Skin and Venereal Diseases, Drs. James Kerr, J. Ford Thompson and Thomas E. McArdle; Practice of Medicine and Physical Diagnosis, Drs. W. W. Johnston, Samuel C. Bussey, G. Wythe Cook, G. Boyd Harrison and Middleton F. Cuthbert; Diseases of Children, Drs. Samuel S. Adams and Geo. N. Acker; Diseases of Throat, Nose and Ear, Dr. Chas. W. Richardson; Diseases of Eye, Dr. W. Holland Milner; Diseases of the Nervous System, Dr. Edmund L. Tompkins; Obstetrics, Drs. J. Foster Scott and Henry D. Fry; Pathology, Bacteriology, etc., Dr. Edward M. Parker.

WASHINGTON OBSTETRICAL AND GYNECOLOGICAL SOCIETY.

The 238th meeting of the Society was held on the 3d instant. Dr. Kelley read a paper on "Fibroid Tumors of the Uterus with Pregnancy." He gave the history of some cases and presented a large fibroid uteri containing a small fetus which he had removed by abdominal section. Dr. Deale read a paper on "Movable Kidney," and reported some cases. Full and interesting discussions followed the reading of each paper. Dr. H. L. E. Johnson presented a colloid cyst of the left ovary and a smaller cyst of the right ovary, successfully removed from a woman 54 years of age.

THE PUBLIC SERVICES.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from December 28, 1895, to January 3, 1896.

Major James C. Worthington, Surgeon, leave of absence granted on surgeon's certificate of disability is extended six months on account of sickness.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending January 4, 1896.

Asst. Surgeons M. S. Guest and C. P. Bagg, ordered to examination for promotion.

Marine-Hospital Changes. Official list of changes of station, and duties of Medical Officers of the U. S. Marine-Hospital Service, for the sixteen days ended December 31, 1895.

Surgeon H. R. Carter, granted leave of absence for twelve days, Dec. 17, 1895.

P. A. Surgeon L. L. Williams, granted leave of absence for fifteen days, Dec. 30, 1895.

P. A. Surgeon W. P. McIntosh, to proceed from Boston, Mass., to Louisville, Ky., and assume command of Service, Dec. 28, 1895.

P. A. Surgeon B. W. Brown, granted leave of absence for nine days, Dec. 17, 1895.

Asst. Surgeon Emil Prochazki, to proceed from Buffalo, N. Y., to Detroit, Mich., for duty, Dec. 28, 1895.

Asst. Surgeon A. R. Thomas, to proceed from St. Louis, Mo., to Boston, Mass., for duty, Dec. 28, 1895.

Asst. Surgeon H. S. Cumming, granted leave of absence for sixteen days, Dec. 16, 1895. Leave of absence extended four days, Dec. 26, 1895.

BOARDS CONVENED.

Board to revise regulations regarding uniforms, Surgeon Fairfax Irwin, chairman, P. A. Surgeons C. E. Banks and B. W. Brown, recorders, Dec. 17, 1895.

Board for the examination of officers for promotion and candidates for admission to the Service, to meet in Washington, D. C., Feb. 10, 1896. Surgeon George Purviance, chairman, Surgeons H. W. Austin and H. R. Carter, recorders, Dec. 30, 1895.

Change of Address.

Beebe, C. E., from Woodland to Watsonville, Cal.
Blitz, A., from Indianapolis, Ind., to Rooms 21-22, Sidle Bldg., Minneapolis, Minn.

Coe, H. W., from 138 E. 29th Street to 115 W. 49th Street, New York, N. Y.
Frisby, E. G., from 229 Geary Street to 803 Sutter Street, San Francisco, Cal.

Hopkins, W. E., from 533 Sutter Street to 803 Sutter Street, San Francisco, Cal.

Hunt, Florence W., from 236 Michigan Avenue to Lexington Hotel, Chicago, Ill.

Rogers, D. F., from Marceline, Mo., to Ottawa, Kan.

Sims, S. N., from St. Joseph, Ill., to Philadelphia Polyclinic, Philadelphia, Pa.

Werner, O. E., from Brillion, Wis., to 517 W. Chestnut Street, Louisville, Ky.

Wood, Horatio F., from Masonic Temple to 1003 Reliance Building, Chicago, Ill.

LETTERS RECEIVED.

Allnut, Henry, St. Paul, Neb.; Armstrong, S. T., Asbury Park, N. J.; Arnold, H. A., Ardmore, Pa.

ADDRESS.

THE IDENTITY OF LUPUS VULGARIS AND LUPUS ERYTHEMATODES.

Chairman's Address, Delivered in the Section on Dermatology and Syphilography, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY ALFRED E. REGENSBURGER, M.D.

CHAIRMAN SECTION ON DERMATOLOGY AND SYPHILOGRAPHY.
SAN FRANCISCO, CAL.

In common with all other branches of medicine, dermatology has felt the result of modern bacteriologic investigations. The brilliant discoveries of Koch, the father of bacteriology, have shattered many idols and put a different aspect upon many things. The advances wrought have been so enormous as to thoroughly have revolutionized some matters. The etiology and pathology of many diseases have been cleared up and the way leading to the elucidation of many mooted questions pointed out.

Lupus vulgaris is one of the questions upon which the search-light of bacteriology has fallen with most beneficial effect. Prior to Koch's time its etiology and pathology were misunderstood. Now nothing is more surely established in medicine than that it is a tuberculosis of the skin. The crucial test of inoculation with pure cultures and with tubercular matter proved the identity of lupus vulgaris and tuberculosis. It is true that animals were successfully inoculated with tuberculosis with matter that was called scrofula before Koch published his experiments but to him belongs the credit of being the modern medical Moses who led his brethren out of the wilderness of darkness.

Koch inoculated and produced tuberculosis with material from tuberculous tissue in over five hundred animals. Other observers corroborated Koch's experiments and brought additional facts to our knowledge. Inoculations of tuberculosis were successfully accomplished in various ways by Koch's disciples.

Cornet, in Koch's laboratory, proved the possibility of inoculating tuberculosis through abrasions of the skin. He demonstrated that lupus tissue and pure cultures of tubercle bacilli when applied to an abrasion of the skin produced a local tuberculosis and also of the adjacent lymphatic glands, followed by a general miliary tuberculosis in most cases. Cornil and Leloir implanted lupus tissue into the peritoneal cavity of guinea pigs and in five out of fourteen cases induced peritoneal and general tuberculosis.

In eleven cases of Leloir and Cornil, and in four cases of Koch, which were examined for the purpose of proving the identity of lupus and tuberculosis, tubercle bacilli were found in every instance. Doutrelepont, Pfeiffer, Koch and Pagenstecher found tubercle bacilli in artificial lupus caused by the implantation of tuberculous products.

Bollinger has shown that the more concentrated

the material and the greater the number of the bacilli in the injection used the more severe and the more rapid was the development of the lesions caused thereby. It was estimated that about eight hundred and twenty bacilli are required to produce fatal tuberculosis in guinea pigs.

The reasons for the identity of tuberculosis and lupus vulgaris are so well stated in Demme's classic brochure upon that subject, that his résumé from that source, making use of the translation as found in Senn's Surgical Bacteriology, page 172, are here given:

- "1. Similarity of histologic structure.
- "2. Presence of the bacillus of tuberculosis in granulation tissue of lupus.
- "3. The production of typical tuberculosis in animals not immune to this disease by the implantation of lupus tissue or the injection of a pure culture of the bacillus of tuberculosis obtained from lupus tissue.
- "4. The fact that patients suffering from lupus are frequently attacked by and die from tuberculosis of other organs.
- "5. The prevalence of tubercular affections among relatives suffering from lupus (hereditary predisposition)."

These views are accepted at the present time by the medical world as the correct ones. Beside the foregoing distinctive anatomico-bacteriologic landmarks, lupus vulgaris has also well defined clinical aspects which belong to it exclusively and serve to differentiate it from every other cutaneous disease and therefore entitle it to recognition as a separate affection.

In spite of all this, claims have been advanced by eminent clinicians, particularly in France, that lupus vulgaris is identical with lupus erythematodes (or erythematosis as some call it); in other words, that these two maladies are one and the same. At first sight there may seem to be no foundation for such a hypothesis, yet upon closer investigation and study one can not resist the view that there are certain similarities between the two diseases, indeed, that there are more similarities than dissimilarities and that the pretensions of relationship between the two merit some consideration.

There appear to exist certain facts which would tend to show that there may be a connection, at least, between these two affections, if they are not really one and the same. There are certainly some points of resemblance. For many lupus vulgaris and lupus erythematodes are but two forms of cutaneous tuberculosis, which must be differentiated. In France they are regarded by many as but varieties of one and the same disease.

The gifted and talented Besnier is the most prominent champion of this opinion. In proof of the correctness of this view its adherents mention the frequent occurrence in those afflicted with lupus

erythematodes, of glandular swellings, tuberculosis of the joints, complicated with tuberculosis of internal organs. Besnier lays great stress upon these complications or sequelæ and explains the fact that their existence is denied upon the ground that they are overlooked and only recognized when particular attention has been called to them. He further makes the statement that it is an every-day occurrence with him to encounter tubercular affections complicating cases of lupus erythematodes, and if not in the party affected, then in the family of the sufferer, or in those with whom he has been in intimate and close connection during the prevalence of a tuberculous affection.

The majority of observers, however, do not affirm the correctness of Besnier's dictum. For those who believe in the identity of lupus vulgaris and lupus erythematodes, there remains this incontrovertible fact which is seemingly a very strong argument, that there exist stages of transition from lupus erythematodes to lupus vulgaris, to such an extent that a lupus erythematodes may be seen passing into a lupus vulgaris so that the symptoms of one affection fade insensibly into those of the other in such a way that the characteristic symptoms of the two affections are combined in one patient.

The two forms may coëxist in the same subject at the same time. Sometimes we see the two running imperceptibly into one another. Vidal believed that a lupus erythematodes may precede or antedate a lupus vulgaris. As Brocq puts it, a lupus vulgaris may begin as a lupus erythematodes.

Besnier insists also strenuously upon this point. There is no doubt but that such cases do occur, where one disease antedates the other and where these two diseases shade so together and lose their clinical identity as to make it impossible to differentiate by looks one from the other. As a very good example of such a condition the following case (taken from Jamieson's book on diseases of the skin, p. 518) is here transcribed:

"In it a well-marked symmetrical lupus erythematosis of the cheeks passed imperceptibly into a lupus vulgaris of the alæ of the nose, with characteristic ulceration and crusting. The two diseases, too, ran inextricably one into another under and behind the lobe of each ear, one, the right, being more prominently affected. The history was unfortunately obscure. This case would show either that the disease may occasionally be transformed in appropriate situations into the other, or that the two forms" (?; the interrogation point is mine,) "of lupus may coëxist in one and the same individual."

This excerpt which occurs a little further on is also worthy of being mentioned:

"There are forms of lupus vulgaris which touch very closely on the limits in that direction of lupus erythematodes, and we could almost construct a series of cases leading by gradual steps from one to the other." That is just what some of the French authors have done.

This would seem to be very seductive reasoning could not the circumstance of the coëxistence of the two affections, contemporaneously, in the same patient be explained upon these two grounds: 1. That a lupus vulgaris may be superadded to an already present lupus erythematodes by inoculation with tuberculous matter, or with the active principle of tuberculosis, the possibility, aye probability, of which re-

ceives additional confirmation in that lupus vulgaris has so frequently its seat on uncovered and exposed parts as the hands and face. Very easy is this when there is an abrasion of the skin or where the skin is in a very susceptible condition, having lost its resistant power by disease and its penetration rendered facile by the persistence of some other affection as lupus erythematodes. What is there to prevent a lupus vulgaris to be inoculated on a patch of lupus erythematodes? All things being favorable to an inoculation, it can not be said that the presence of lupus erythematodes renders the subject immune to inoculation with lupus vulgaris. Even Dr. Besnier virtually admits this when, in dilating upon the treatment of lupus vulgaris, he opposes the use of cutting or surgical methods because they tend to a local tubercular reinfection and thus increase the number of those suffering from phthisis. If this be true in a patient suffering from lupus vulgaris, how much the more so in one affected with lupus erythematodes? 2. The presence of two different cutaneous affections in the same subject at the same time does not prove that they are related or are one and the same disease, were they even met with oftener together at the same time in the same individual, instead of very rarely and exceptionally so as in the two diseases under discussion.

Different affections are encountered in the same subject in dermatology quite frequently. We might just as well say that because a person affected with acne becomes infected with scabies, that these two affections are related to each other.

We must admit that these cases are exceptional, and where such a state of affairs exists it is simply a coincidence and has no etiologic or other significance. The anatomic and histologic data of lupus vulgaris and lupus erythematodes are entirely different.

Bacteriologically they diverge as wide if not wider. Leloir and no other competent observer has ever been able to find the tubercle bacillus in lupus erythematodes and never has lupus erythematodes been transferred to man by inoculation with tubercular matter or with pure cultures from tuberculosis. They have nothing which links them together except the name, or rather the misnomer lupus, a term which is not a desirable one, as it gives no idea either of their etiology, histology or of anything else connected with them. We are therefore forced to these conclusions: That lupus vulgaris and lupus erythematodes are two entirely separate and distinct diseases. That lupus vulgaris is a local tuberculosis of the skin. That the term lupus vulgaris should be eliminated from our nomenclature of diseases, and the affection in question designated as tuberculosis cutis qualified by the name of the part of the surface affected. That the term lupus erythematodes may be retained, as it has usage and custom to recommend its continuance, until we shall have a better understanding of the pathologic processes of the disease, with the knowledge that it refers to a chronic inflammatory process of the skin of whose exact nature we are ignorant of at the present time.

DISCUSSION.

DR. OHMANN-DUMESNIL, of St. Louis, said that the tubercle bacilli were never found in lupus erythematosis, except as an accidental infection.

DR. BELKLEY, of New York, expressed the opinion that he agreed with Hebra that there was no relation between lupus

vulgaris and lupus erythematosus. He referred to two cases in his own experience where lupus vulgaris had developed in patients with lupus erythematosus, but he believed it was by the subsequent inoculation of the tubercle bacilli on the lupus erythematosus base. He also thought that in Paris true lupus vulgaris of a superficial character was often called lupus erythematosus, and so confusion was apt to result as to the relationship between the two diseases. He had used phosphorus with success, in the form of Thompson's solution, with glycerin and alcohol; whereas the treatment produced no effect on lupus vulgaris. He considered that lupus erythematosus was a congestive seborrhea. In one perfectly typical case of lupus erythematosus on the hands and face the patient developed pulmonary tuberculosis, and after watching her for ten years she died of consumption.

ORIGINAL ARTICLES.

FOUR RECENT CASES OF EXTRA-GENITAL SYPHILIS IN PRIVATE PRACTICE.

Read in the Section on Dermatology and Syphilography at the Forty-sixth Annual Meeting of the American Medical Association at Baltimore, Md., May 7-10, 1895.

BY L. DUNCAN BULKLEY, A.M., M.D.

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL; CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL, ETC.

While cases of syphilis innocently acquired are not of very infrequent occurrence, and the number of reported cases is increasing rapidly, the following recent instances in private practice are thought to be of sufficient interest to warrant placing them on record. They serve to call attention to the dangers which arise from the disease on every side, and to illustrate the diverse locations where the initial lesion of syphilis may be found, as well as the modes by which the poison may enter the system:

Case 1.—Chancre of the Cheek. Mrs. W., aged 24, was sent to my office in consultation May 28, 1894, on account of a sore on the right cheek, just below the zygoma, which had refused to heal. It had begun six weeks previously, as a small pimple like a mosquito bite, which had soon broken down, leaving a raw surface, which increased in size to the time of the visit.

When first seen the sore was almost circular, about half an inch in diameter, pouting above the level of the skin a little and with considerable induration: the surface was partly exposed and presented a red, glairy appearance, and was partly covered with a brownish crust; the glands beneath the jaw on that side were enlarged and hard. A little later she called with an exquisite maculo-papular syphilid.

The husband was found to be syphilitic, in an acute stage, but the exact mode of inoculation was not learned: it is readily understood, however, how the small abrasion following the first lesion, which was presumably non-specific, could easily become inoculated during the intimate relations of the married life, from mucous patches in the mouth of the husband.

She was then pregnant four months, and on Jan. 22, 1895, she was sent to me again with the child, then aged four months, presenting the perfect picture of inherited syphilis: there was an enormous amount of papulo-squamous eruption, involving the head and limbs mainly, including the palms and soles, with the drawn "old man" facies so commonly seen. The child had been born free from eruption, but had had "snuffles" almost since birth: the eruption had developed one month before the visit, when the child was three months old.

Case 2.—Chancre of the Finger. Dr. D., aged 29, consulted me Jan. 14, 1895, for the diagnosis of a very general macular eruption, which had begun three days previously, on the abdomen, and rapidly increased, until at the time of the visit, it covered the body and limbs very generally. It was attended with a very general adenopathy, which followed pretty quickly upon an enlargement of the glands of the right elbow and axilla in connection with the local sore on the right middle finger. He had had some rise of temperature for a length of time: a month previous it had registered 100 degrees, and was 99.2 a day or two before the visit. For two weeks he had had pain and tenderness over the sternum.

The origin of the sore was a little interesting. He had for some time had an ordinary wart on the pulp of the last phalanx of the right middle finger, near the center, but as it annoyed

him in gynecologic work (he having a large dispensary, obstetric and gynecologic practice) he had attempted to get rid of it. For this purpose he had burned it with nitric acid in the preceding September. He had covered the lesion with cotton, with collodion over it, but it suppurated, and the wound was again cauterized with nitric acid three or four weeks later, and again carefully covered with cotton and collodion. As it did not heal he burned it again with nitric acid, four or five weeks previous to the visit, when it appeared to heal: a small crust, however, remained in the center, and a considerable area of hardness beneath. He was not conscious of having exposed it to infection, and as he had feared this because of the nature of his practice, he kept it carefully protected.

When examined there was a small crust, hardly a line in diameter, in the center of the flexor surface of the last phalanx of the right middle finger, and beneath it an induration, about one-third of an inch in diameter, rather movable: there was little redness and no pain, and, were it not for the adenopathy at the bend of the arm and that in the axilla, the size of a chestnut, and the general symptoms, it would have been hardly possible, even for one familiar with extra-genital lesions, to have given a positive diagnosis of chancre of the finger. It is needless to say that the subject of venereal infection was gone over, and that there had been no venereal exposure nor was there other initial lesion of syphilis elsewhere.

Case 3.—Chancre of the Right Nostril. Mrs. C., a previously healthy lady, was brought to my office with what had been supposed to be an epithelioma of the right nostril, on May 18, 1894. As I learned from other sources, her son had had active syphilis, and his wife had been confined in the preceding December, the child soon developing hereditary syphilis, of which it died on April 30. She had had almost constant care of her grandchild, up to its death, it having abundant eruption, mouth lesions, etc.

On April 15, she had first noticed a soreness in the right nostril, which had increased to the time of the visit, the first sensation was like a "cold in the nose," the nostril being closed by edematous swelling, and very shortly there was much pain through the right temple and back of the head.

When first seen there was a hard mass in the right nostril, quite within it, against the septum, which blocked the lumen to a considerable degree, so that she did not breathe through it. The lower edge was quite sharply defined, and, as far as could be felt, it presented a hard cartilaginous feeling; the surface of most of it was superficially ulcerated.

There was already a slight macular eruption about the neck, and a few large flat lesions behind the right ear. The lymphatics beneath the right jaw were very much enlarged, and there was also some adenopathy behind the right ear.

Feeling quite sure of the diagnosis on the first examination, it was still thought best to defer instituting specific treatment until further study of the case and until I could learn more of the probable source of infection. I gave her only a soothing lotion and ointment. It was after the second visit that I learned from another son in regard to the syphilitic child and her care of it.

About one week later I saw her again when the eruption was found to have increased greatly over the back, chest, and arms, and was unmistakable. She had some general osteoscopic pains, and tenderness of the shins. The ulcer was about the same, little if any influenced by the local treatment. She was then given a tablet containing one grain of mercury and chalk every two hours.

Two weeks later it was noted that she was feeling very much better in every way. The ulcer in the nose was greatly improved and she could breathe through that nostril. The eruption had already somewhat faded. She had averaged about eight tablets daily, sometimes had taken ten.

Three weeks later the ulcer in the nose had entirely healed and she breathed almost perfectly through that nostril. There had been no local mercurial treatment, only a little mild camphor and zinc ointment had been applied from the first. The eruption had then almost entirely faded, but there were still glandular swellings beneath both jaws, and the shins were yet tender. She had diminished the tablets to two or three daily, for the previous week, because the teeth felt sore. On July 28 the sore was noted as completely healed, with a depressed surface where it had existed: the eruption had quite vanished, but there were some mucous patches on the lips. She has been seen occasionally since that time, and as she is rather neglectful of treatment she occasionally has had manifestations of her disease. In regard to the source of her infection, although she could not trace it to any particular event or action, there can be no question but that in her ministrations to her syphilitic grandchild she carried the poison to the nostril, probably with the finger.

Case 4.—Chancre of the Left Tonsil. Mr. E., aged 59, was brought to me by his physician on May 14, 1894, on account of a very general maculo-papular eruption covering the body and extremities.

He had been suffering for four weeks from very severe general pains in the neck and back, and also aching of the bones all over. This had been considered rheumatic or neuralgic by his physician, and he had had plasters in various places and treatment with the Turkish bath, Rochelle salts, quinin, colchicum, etc. He had also complained of soreness of the throat much of the time, and a cough. Four or five days before his visit, an eruption began on the forehead which had increased rapidly up to the time of his visit, when it had become very general. There could be no mistaking the maculo-papular sypphilid which he presented, which extended over his bald head, upon the trunk and limbs, even on the palms.

In searching for the source of infection, examination of the genital region showed no trace of a primary lesion, and it was learned that he had had no connection for a year. Nor was there any sign of a chancre, past or present, on any other external part of the body, nor had he had any sore.

He had had, however, trouble on the left side of the throat, with swelling beneath the left jaw, which latter had, however, about disappeared at the time of the visit. There was not very much to be seen in the throat except a dull redness of the left tonsil, with a little superficial ulceration. There was no record made as to hardness, and the facts regarding this have escaped me. But from a total absence of any other possible site of infection, and from the amount of trouble he had had on the left side of the throat, with the adenopathy beneath the jaw on that side, I have no doubt whatever that the infection took place in that locality. Among the fifteen cases of chancre of the tonsil, which I recently reported,¹ the tonsillar lesion was relatively insignificant in some instances, as we know it often to be in the genital region and elsewhere; although it may often produce large tonsillar lesions, giving rise to much trouble and pain, this is not at all necessary to secure infection, and it is well known that chancre within the cavity of the mouth, especially in children, may very frequently be overlooked, until other signs of syphilitic infection call attention to their presence.

All the localities represented in these cases have been repeatedly observed to be the seat of syphilitic infection. Few realize, however, with what relatively great frequency the point of entry of the syphilitic poison is in the region of the mouth and throat. Thus, in my recent study of the subject,² out of a total of 9,058 extra-genital chancres, I found records of no less than 307 cases of chancre of the tonsils; there were also 264 cases where the location of the chancre was "deep oral and nasal;" and in 734 cases it was recorded as in the "buccal cavity." These, together with 157 cases on the tongue and 42 on the gums, make no less than 1,504 cases where infection took place within the cavity of the mouth, or over 16.5 per cent. of the entire number analyzed. Adding these to 1,810 cases of chancre of the lip, there collected, we have a total of 3,314 cases or 36.5 per cent. in which infection occurred in the region of the mouth. With this very great relative frequency in this locality, it is well to be on the lookout for instances where the poison has been here introduced.

In addition to the four cases here detailed, where the site of non-venereal infection was definitely known, several other cases have been observed in my private practice where there was every reason to believe that the disease was thus acquired, but where even careful investigation failed to demonstrate with sufficient certainty for report the exact location of the primary sore; some of these have been very interesting and puzzling, but need hardly be detailed here. This is quite exclusive of instances of marital or hereditary syphilis of which a number have also been under observation.

Including the four cases above narrated, of extra-genital chancre, no less than 120 instances of this form of infection have come under my personal observation and care. The histories of 116 of them are given in the recent work referred to on "Syphilis in the Innocent." For those who may not have seen the list, I will present it here in full, in order to illustrate the frequency with which other portions of the body than the genital region may become the seat of the initial lesion of syphilis. These instances occurred among something over 2,000 cases of syphilis seen in various forms and states; the extra-genital infection being demonstrated in about 6 per cent. of all the cases seen.

PERSONAL CASES OF EXTRA-GENITAL CHANCRES.

Location.	Male.	Female.	Total.
Chancre of the lip	20	31	51
" " tonsil	9	7	16
" " finger	14	2	16
" " breast		8	8
" " tongue	3	3	6
" " cheek	5	1	6
" " eyelid	3	1	4
" " chin	3	1	4
" " hand	1	1	2
" " nose	1	1	2
" " ear	1		1
" " temple		1	1
" " neck		1	1
" " forearm	1		1
" " sacral region	1		1
Total	62	58	120

Of these 120 cases it will be seen that the males are slightly in the preponderance, which is rather contrary to the common belief. I think, however, that these figures, although small, probably show the correct proportion; as a rule, the patients with syphilis have come on account of the eruptions present some time during the course of the disease, or because of the local sore present, which is commonly supposed to be a skin lesion. Therefore, both the proportion of extra-genital chancres, and the relation of the sexes are more likely to be correct than in an experience drawn from venereal practice alone, where many of the extra-genital sores would not present themselves.

The cases here narrated, and those represented in the table also, show how careful we should be when having to do with syphilis in a patient, not to necessarily charge the individual with wrong doing, for the disease is much more frequently acquired innocently than is commonly thought. Among the cases of syphilis presenting themselves in my private and public practice, about 6 per cent., or one person in sixteen or seventeen had received the disease through extra-genital infection; when we come to include the cases of marital and hereditary syphilis it is quite probable that over 10, perhaps 15 per cent. of all cases acquire the disease quite innocently of all sexual transgressions.

4 East 37th Street, New York.

ULCERATIVE SYPHILID OF THE PHARYNX.

Read in the Section on Dermatology and Syphilography, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY A. RAVOGLI, M.D.

CINCINNATI, OHIO.

Syphilis attacks the pharynx like any other organ, and cases have been reported in which the initial lesion was found in the upper pharynx, the infection

¹ Transactions Medical Society, State of New York, 1893.

² Syphilis in the Innocent (Syphilis Incontinentum), Bailey & Fairchild, N. Y. 1891.

being communicated by means of the Eustachian catheter. In the secondary stage syphilis attacks the pharynx as a result of a specific erythema, which from the soft palate and the tonsils spreads to the surface, and sometimes it produces a catarrhal inflammation without characteristic specific symptoms. Mucous patches which we so frequently meet with on the tonsils, faucial pillars and soft palate, very rarely are found on the wall of the pharynx. Zeissler never saw a mucous patch on the pharynx, and in my experience I do not remember to have seen mucous patches on this region.

Ulcerative syphilid affects the pharynx at an advanced secondary period. As the affection is not a common one, I find it worthy to be submitted to your attention.

In a large number of syphilitic patients in my practice I find only four cases of this peculiar lesion recorded. All four were men and all used to drink alcoholic liquors and chew tobacco.

The affection began at the time when the patients were in apparent good health, two to three years after the infectious chancre had first appeared. Feverish reaction, and an intense pain in the act of deglutition and in the articulation of words were constant symptoms in each case. The lesion consisted of an inflammatory prominence, of the size of a dime, dark red, which soon showed ulceration in the middle. The center of the ulcer, like a crater, was deep and covered with a yellow diphtheroid detritus; the edges, brown-red, were sharply cut and elevated above the surface of the mucous membrane, and were surrounded by an inflammatory halo. Recovery took place with a whitish superficial scar, which remains always perceptible.

Case 1.—J. S., 25 years old, butcher by trade, man of a splendid physical constitution, had hard chancre on the internal surface of the prepuce in February, 1885. In May of the same year had a papular eruption accompanied by mucous plaques of the mouth and of the anus. He was subjected to intramuscular injections of sublimate 1 per cent. After twenty injections every symptom had entirely disappeared. He was in good health, had no syphilitic symptoms, and refused further treatment. On March 19, 1886, came again to consult me for sore throat and fever, which he thought due to a cold. He was somewhat emaciated. A superficial examination of his throat did not reveal any specific lesion of the soft palate, the tonsils were normal, but the posterior wall of the pharynx looked very red. As speaking was difficult and the voice had a nasal tone, I subjected him to a rhinoscopic examination. On the upper portion of the pharynx behind the velum palati, I found an ulcer of the size of a five cent piece deeply and sharply cut in the mucous membrane, covered with a yellow diphtheroid detritus with elevated swollen edges, surrounded by an inflammatory halo. The diagnosis was not difficult, knowing the preceding history. A mixed treatment of inunctions with mercurial ointment and large doses of potass. iodid, combined with local applications of peroxid of hydrogen for cleansing the surface and then blowing powdered iodoform, soon brought about recovery.

Case 2.—M. P., Italian laborer, 37 years old, good constitution, used to smoke pipes and drink whisky, came to my clinic on July 15, 1893. He complained of excessive pain in attempting to swallow anything, had some remittent fever and was wasting away rapidly. The man had been under my treatment nearly one year before for papular syphilid, which yielded easily to fifteen intramuscular injections of sublimate 1 per cent. There remained a stubborn sternal neuralgia, and for this he took iodid of potassium, followed by pills of protoiodid. The patient was well, and I did not see him any more until said date, nearly one year after the first treatment.

At present the patient is very pale, of sallow hue, emaciated; a few enlarged glands can be found on the cervical region as evidence of the past trouble. No mucous patches in the mouth, none on the throat, which is scarcely red. By the aid of the tongue depressor a vivid redness can be seen at the base

of the pharynx, which surrounded a round ulcer the size of a quarter of a dollar. The edges of the ulcer were sharply cut, inflamed, elevated on the surface of the mucous membrane, the hollow of the sore showed a yellow diphtheroid appearance, discharging purulent matter. The patient was treated with mercurial inunctions and iodid of potassium in large doses. Locally the ulcer was washed with peroxid of hydrogen and covered with iodoform powder. In twenty days the ulcer had completely healed up and the patient was discharged.

Case 3.—W. F. F., a young man 27 years of age, barkeeper by occupation, of good and sound constitution, has always enjoyed good health. In April, 1892, he called on me with a syphilitic roseola. The initial lesion of syphilis was found on the second phalanx of the thumb of the right hand on the internal side. It was an ulceration half cicatrized on an indurated base. The epitrochlear gland of that side was hard and swollen. The patient received twenty intramuscular injections of sublimate 1 per cent. and on the ulcer emplastrum hydrargyri was daily applied. In a short time the roseola had completely disappeared and the ulcer of the thumb thoroughly cicatrized. The patient was discharged, with the advice to take two pills a day of protoiodid hydrarg. for two months longer.

In January 1893, he came again with a pustular syphilid. A few ectymatous ulcerations were scattered on the scalp and on the face. He was subjected to another course of treatment, and when better was not seen again.

The patient kept on in his occupation and used to drink a good deal of whisky and to smoke. On August 1893, he came to my office complaining with difficulty of speaking and swallowing. He had fever and was greatly emaciated. Pushing down the tongue with the depressor a round ulcer could be seen on the base of the pharynx of the size of a quarter of a dollar, surrounded by an inflammatory halo, with swollen edges, sloping down to a yellow grayish bottom. A mixed general treatment was begun, and local washing with peroxid of hydrogen and dressing with iodoform powder in short time brought about recovery.

Case 4.—In my hospital service, T. P., on February 18, 1895, was admitted with one of the same ulcers on his pharynx. He had acquired syphilis nearly three years before, and had been treated in the same institution. He had high fever and experienced great difficulty in swallowing.

This man like the others had been used to drink liquors and was in the habit of chewing tobacco.

The treatment, general and local, was like that of the other cases and in three weeks the ulcer was perfectly cicatrized and the patient left the hospital.

In the literature on syphilis of the pharynx there is not much said about this kind of lesions. Seifert¹ speaks of ulcerations, hard chancres, mucous patches of the tonsils and palate, but does not speak much of the pharynx. In the same way J. N. Mackenzie—"Syphilis of the Upper Air Passages"—speaks of secondary lesions of the pharynx as a result of lesions of the surrounding parts, mentions tertiary lesions, but nothing definite on this affection.

In my opinion, I find this ulcerative syphilid of the pharynx to be rather a rare one, considering that in a large number of syphilitic patients only four showed this affection. All the four cases were in men, and I never met with this affection in women.

I find this affection of great importance for the diagnosis, for the possibility of being exchanged with ulcerations of diphtheritic or of any other origin.

I do not consider the affection as a true tertiary lesion, but only as a late secondary ulceration. From the habits of the four patients I should come to the conclusion that the use of alcoholic liquors and chewing tobacco has a great deal to do with the production of this ulcerative affection. The irritation produced on the inferior portion of the pharynx by the passage of the alcohol and of the saliva saturated with the irritant tobacco juice is sufficient cause to excite a syphilitic inflammatory affection resulting in ulceration.

The affection is very painful, prevents the patient

¹ Syphilis der oberen Luftwege. Deutsche Med. Wochens., 1893.

from eating, and in all the cases was accompanied with fever.

The ulcer heals up readily when with a general antisyphilitic treatment a local antiseptic medication is used. A superficial, whitish scar is the result of this ulcerous syphilid, which remains always perceptible on the mucous membrane. I have never seen deep scars resulting from this affection, like those from the true gumma of the pharynx, which may result in a stricture and impairment of the function of the organ.

The coexistence of fever with this affection and the stormy inflammatory symptoms cause me to place it rather among the secondary symptoms of syphilis than among the tertiary. In the tertiary affections we see more tendency to a slow process of hypertrophy, as it is in the production of gumma, while in all secondary lesions we see a tendency to inflammation.

The local irritation as mentioned above, from the use of tobacco and alcohol, is the most effective factor in producing this peculiar ulcerative lesion of the pharynx.

LUPUS TREATED BY GALVANISM.

(ILLUSTRATED BY PHOTOGRAPHS.)

Read in the Section on Dermatology and Syphilography, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY B. MERRILL RICKETTS, M.D.

CINCINNATI, OHIO.

So much has been said concerning the various forms of lupus that I refrain from speaking of it from any other than a personal point of view. I would refrain from speaking of any other treatment than is herein mentioned, especially as I presented a paper to the Pan-American Congress upon the extirpation of lupus tissue.

It is conceded that constitutional treatment avails nothing in this disease, and I think that I am safe in saying that caustics and the curette are of little use unless carried to the extreme.

I wish now merely to report one of several cases in which I have used the galvanic needle with the greatest satisfaction. There is, however, one great objection to its use—that is the length of time required—but as the treatment is not imperative, the disease being exceedingly slow in its progress, I do not think that good results should be sacrificed for the want of time.

The length of time required to destroy a given area affected with lupus, depends upon the degree of tolerance on the part of the patient.

However, if the patient is an adult, or even a child, the amount of galvanism used may be almost without limitation, if a small amount of cocain has been previously injected within and about the affected area. In this way the tissue may be destroyed more rapidly.

Where there are several lesions to be treated, the effects of cocain in any one will pass off before it is necessary to inject another. In this way the length of time of a sitting may be indefinite, and the amount of cocain practically disregarded, if the amount used in any one lesion is not more than absolutely necessary to produce anesthesia.

As stated on a previous occasion, an operator should accustom himself to the use of but one kind of cocain, and he should familiarize himself with the

Mrs. M., white, aged 51, born in Ireland, mother of several healthy children. Lupus erythematosus began at the age of 30 on the face and neck. Treated for years for syphilis without result. Twenty-two lesions treated by galvanic needle, with twenty-one cured, not having returned in eighteen months; twelve excised with knife; three returned and were afterward treated by galvanic needle and did not return.

use of that kind, which should always be made into solution at the time of the operation.

By following these few thoughts I can hardly conceive of any accident occurring, or any pain resulting from the use of the needle.

The means of determining when the diseased tissue is destroyed are rather difficult to understand—experience counting more than all other things in determining that.

The insertion of the needle should be in every direction through the diseased tissue, and the application continued until all evidence of redness has disappeared.

The needle should extend through the integument, it not being necessary to attack anything beneath it; at least, this has been my experience.

I believe that galvanism is to the lupus bacillus

suggest. This she readily consented to do. There was at this time about fifty-eight lesions, both large and small. I excised twelve of the smaller ones with the knife and destroyed twenty-two, several of which were the largest, with the galvanic needle.

Three of those excised by the knife returned, while there was but one of the twenty-two destroyed by the needle which returned, that one being upon the forehead; its location caused me to discontinue the current before the lesion was entirely destroyed. I had reason at the time to believe that it would return. All of the four lesions returned within six months, and the three which had been excised were destroyed by the needle. The one on the forehead, however, has never been interfered with, and allowed to develop *ad libitum*. It has increased in size about one-fifth.

what arsenic is to the cells of epithelioma. I have not been able to find any other influence so satisfactory in their destruction.

The principal case in question is as follows:

Mrs. M., white, aged 51, born in Ireland, the mother of several healthy children, consulted me in the summer of 1889 for a number of lesions about the face and neck, which had existed about sixteen years and had been considered by many professional gentlemen as of syphilitic origin. She had used large quantities of iodid of potassium and mercury, both internally and externally, without any effect whatever. It had, however, been diagnosed as lupus vulgaris by one or two physicians in the community.

During my absence, my assistant again placed her upon the protiodid and large doses of iodid of potassium, without any result. She was under our care for several months and then disappeared from my notice. In the fall of 1893, she again consulted me and I then advised her to accept whatever I might

Of the thirty-four lesions destroyed, but one remains to be seen.

Sickness, death, and other misfortunes in her family have rendered it impossible for me to continue my work in this case, which I regret exceedingly.

I herewith present the photographs taken six months after the treatment had been commenced. There are, of course, cicatrices as the result of the destruction of tissue.

It is now twenty months since I began the work, and but one of the fifty-eight lesions remain—that upon the forehead—which had been attacked by either the needle or knife.

I hope, in course of time, to make a subsequent report upon this case, and I herewith submit it for your consideration, fully realizing the discouraging feature of any treatment in any form of lupus.

"The Trinidad."

SUGGESTION AS AN IDEO-DYNAMIC FORCE.

Read at the meeting of the Chicago Academy of Medicine.
Dec. 15, 1885.

BY W. XAVIER SUDDUTH, M.A., M.D., F.R.M.S.
FELLOW OF THE CHICAGO ACADEMY OF MEDICINE.
CHICAGO.

Among the many curative agents that have been brought forward during the last few years none is attracting wider attention at the present time than the subject before us. Technically speaking suggestion is the active principle of all psycho-therapeutic measures. Its discovery was the result of years of labor in the laboratories of the biologist and experimental psychologist. In the fullest sense it is therefore the legitimate child of science and not an outcast as some would try to make out. With such parentage it behooves us to look well into its claims and study the phenomena of its manifestations.

Like many other curative agents discovery of suggestion came about through close observation of pathologic conditions. Just as the study of bacteriology in its relation to pathology resulted in the formulation of the germ theory of disease and the subsequent discovery of antiseptics and serum therapy, so has the study of morbid psychology established the value of suggestive therapeutics in the treatment of functional derangements.

The late Daniel Hack Tuke was the Virchow of psychologic medicine and his works stand to-day as classic monuments to his memory. His labors extending over a full quarter of a century have thrown a flood of light upon the influence of the mind on the body in the production of disease. He was a pioneer in the field of morbid psychology and while he was preceded by great lights, yet his light showed clear to the end.

Unzer, as early as 1771, wrote "Expectation of the action of a remedy often causes us to experience its operation beforehand," and the immortal John Hunter, whose breadth of intellect enabled him to grasp many scientific truths generations ahead of his time, lectured to his classes in 1786-7 on the subject of "Attention and Expectation." Johannes Muller in 1838, gave added light to our understanding of the influence of mental states over bodily functions. He held as a general fact "that any state of the body, which is conceived to be approaching and which is expected with an unfailing confidence, will be prone to ensue, as the mere result of an idea, if it do not lie beyond the bounds of possibility." Braid, in 1841 threw a flood of light on the influence of the mind upon the body by his investigations into mesmerism, which he rechristened hypnotism. In the compiling of his book "Influence of the Mind upon the Body" Dr. Tuke drew upon an extended personal experience and from over one hundred authorities upon the subject. I should be vain indeed to hope to add to the scope of his labors in that direction but such is not my intent; in this paper my sole purpose is to offer a possible explanation of the method of application and the operation of suggestion in the treatment of disease.

In order that we may proceed intelligently to the consideration of the subject let us first seek to establish a definition for suggestion.

James Mark Baldwin, M.A., Ph.D., Stuart Professor of Psychology in Princeton University, in a recent work (1895) on the "Mental Development in the Child and the Race," discusses the subject and

defines suggestion "as the tendency of a sensory or an ideal state to be followed to a motor state" and says "it is typified by the abrupt entrance from without into consciousness of an idea or image, or a vaguely conscious stimulation, which tends to bring about the muscular or volitional effects which ordinarily follow upon its presence." Janet defines suggestion as "a motor reaction brought about by language or perception." This narrows the field to certain classes of stimulations, well defined in consciousness, and overlooks the more subtle suggestive influences emphasized by the Nancy school (of theorizers). Schmidkunz makes it: *die Herbeiführung eines Ereignisses durch die Erweckung seines psychischen Bildes.*¹ This again makes a mental picture of the suggested "event" in consciousness necessary, and, besides, does not rule out ordinary complex associations. It neglects the requirement insisted upon by Janet, *i.e.*, that the stimulus be from without, as from hearing words, seeing actions, objects, etc. Wundt says: *Suggestion ist Association mit gleichzeitiger Verengerung des Bewusstseins auf die durch die Association angeregten Vorstellungen.*² In this definition Wundt meets the objection urged against the definition of suggestion in terms of complex association, by holding down the association to a "narrowed consciousness;" but he, again, neglects the outward nature of the stimulus, and does not give an adequate account of how this narrowing of consciousness upon one or two associated terms, usually a sensori-motor association, is brought about. Ziehen says: *In der Beibringung der Vorstellung liegt das Wesen der Suggestion.*³ Here we have the sufficient recognition of the artificial and external source of the stimulation, but yet we surely can not say that all such stimulations succeed in getting suggestive force. A thousand things suggested to us are rejected, scorned, laughed at. This is so marked a fact in current theory, especially on the pathologic side, that I have found it convenient to use a special phrase for consciousness when in the purely suggestible condition, *i.e.*, "reactive consciousness." The phrase "conscious reflex" is sometimes used, but is not good as applied to these suggestive reactions, for they are cortical in their brain seat, and are not as definite as ordinary reflexes. Baldwin continuing says, "For my present purposes, the definition I have given from my earlier work is sufficient, since it emphasizes the movement side of suggestion. The fundamental fact about all suggestion—not hypnotic suggestion alone, which some of the definitions which I have cited, have exclusive reference to—is, in my view, the removal of inhibitions to movement brought about by a certain condition of consciousness, which may be called suggestibility. The further question, what makes consciousness suggestible, is open to debate. There are two general statements—not to elaborate a theory here however—which are not done justice to by any of the earlier theories. We may say, first, that a suggestible consciousness is one in which the ordinary criteria of belief are in abeyance; the coefficients of reality, to use the terms of my earlier discussion of belief, are no longer apprehended. Consciousness finds all presentations of equal value, in terms of uncritical reality-feeling. It accordingly responds to them all, each in turn,

¹ Psych. der Suggestion.

² Hypnotismus u. Suggestion.

³ Philos. Monatschrift, xxix., 1893, p. 489.

readily and equally. Second, this state of things is due primarily to a violent reaction or fixation of attention, resulting in its usual monoideism, or 'narrowing of consciousness.'"

Professor Baldwin's studies as outlined in his book, were made upon his own children and constitute the most elaborate line of research on the subject yet published, and beginning as they do with the dawn of consciousness they are specially valuable as being divested of any suspicion of auto-suggestion, the result of previous education. On this point he says, "Observation of an infant for the first month or six weeks of its life leads to the conviction that its life is mainly physiologic. The vacancy of consciousness as regards anything not immediately given as sensation, principally pleasure and pain, precludes the possibility of ideal suggestion as such. The infant at this age has no ideas in the sense of distinct memory images. Its conscious states are largely affective. Accordingly, when the reactions which are purely reflex and certain random impulsive movements are excluded, we seem to exhaust the contents of its motor consciousness."

"Yet even at this remarkable early stage, first six weeks, H. was found to be in a degree receptive of suggestion,—suggestion conveyed by repeated stimulation under uniform conditions. In the first place, the suggestion of sleep began to tell upon her before the end of the first month. Her nurse put her to sleep by laying her face down and patting gently upon the end of her spine. This position soon became itself not only suggestive to the child, of sleep, but sometimes necessary to sleep, even when she was laid across the nurse's lap in what seemed to be an uncomfortable position."

On the point as to what constitutes a suggestion we have long held that anything that suggests or conveys an idea to the sensorium is a suggestion. (*Vide* JOUR. AMERICAN MED. ASSOCIATION, Nov. 30, 1895.) In this position we are supported by Professor Baldwin also who, in discussing various sleep suggestions, says: "From the first month on, there was a deepening of the hold upon the child H. of the early method of inducing sleep. The nurse, in the meantime, added two nursery rhymes. Thus position, pats, and rhyme sounds were the suggesting stimuli. Not until the third month, however, was there any difference noticed, when the same suggestions came from other persons. I myself learned, during the first month, to put her asleep, and learned with great difficulty, though pursuing the nurse's method as nearly as possible. Here, therefore, was a suggestion, from the personality of the nurse, her peculiar voice, touch, etc., of which mention is made more fully below. At this time I assumed exclusive charge of putting H. to sleep, in order to observe the phenomena more closely. For a month or six weeks I made regular improvement, reducing the time required from three-quarters of an hour to half an hour, finding it easier at night than at midday. This indicated that darkness had already become an additional sleep suggestion, probably because it shut out the whole class of sensations from sight, thus reducing the attention to stimulations which were monotonous. I found by accident, in this connection, the curious fact that a single flash of light would often put H. immediately to sleep when all other processes were futile. In her fifth month I despaired one evening, after nearly an hour's vain effort, and lighted the

gas at a brilliant flash unintentionally. She closed her eyes by the usual reflex, and did not open them again, sleeping soundly and long. I afterwards resorted to this method on several occasions, carefully shielding her eyes from the direct light rays, and it generally, but not always succeeded. Shortly after noticing this in the columns of *Science* (Feb. 27, 1891), I heard from a prominent psychologist that his wife could confirm the observation from experience with her own children.

"In the following month (sixth), I reduced the time required day or night, to about a quarter of an hour, on an average. In this way I found it possible to send her off to sleep at any hour of the night that she might wake and cry out. I then determined to omit the patting, and endeavor to bring on sleep by singing only. The time was first lengthened, then greatly shortened. I now found it possible (sixth to seventh month) to put her to sleep, when she waked in the dark, by a simple refrain repeated monotonously two or three times. In the meantime she was developing active attention, and resisted all endeavors of her nurse and mother, who had been separated from her through illness, very stubbornly for hours, while she would go to sleep for myself, even when most restless, in from fifteen to thirty minutes. This result required sometimes firm holding down of the infant and a determined expression of countenance."

"At the end of the year, this treatment being regular, she would voluntarily throw herself in the old position at a single word from me, and go to sleep, if only patted uniformly, in from four to ten minutes. This continued through the second year, even when she was so restless that her nurse was unable to keep her from gaining her feet, and when she screamed if forced by her to lie down. The sight of myself was sufficient to make her quiet, and in five minutes, rarely more, she was sound asleep. I found it of service, when she was teething and in pain, to be able to thus give her quiet, healthful sleep."

The Dictionary of Psychologic Medicine says: "Suggestion in its widest sense may be defined as an act by which an idea is introduced into and accepted by the sensorium. Every idea is transmitted to the brain by a sense organ, but it does not, however, become a suggestion unless it is accepted, and this acceptance often takes place by reason of the tendency to credence inherent in the human mind. The idea may be transmitted directly by the suggested speech to the brain as a direct suggestion; or, again, it may be created by the brain in consequence of an impression received—indirect suggestion. In the latter case psychic individualism comes into play, so that the same impression may give rise to different suggestions, because each brain-reaction in its own peculiar way transforms the impression differently. The first impression is the germ of the suggestion, and is elaborated by the fertile mental soil. The suggestion having been made, and the idea accepted by the brain, there then follows a centrifugal phenomenon—every suggested idea which has been accepted tends to become an act—i. e., sensation, visual image, movement, action, passion, etc., or in other words, every cerebral cell stimulated by an idea stimulates those nerve-fibers which are to realize this idea. This is the law of ideo-dynamism, as we call it. No one has understood this law better, and illustrated it by more numerous examples, than Dr. Hack Tuke in his

'Influence of the Mind on the Body.' The idea thus may become a sensation—*e. g.*, the idea of having fleas causes the sensory phenomenon of itching. The idea may become an image—*e. g.*, hallucinations during sleep and when awake. The idea may become a visceral sensation or organic action—*e. g.*, the administration of bread-pills as a purgative, vomiting by a substance believed to be an emetic, etc.; or the idea may become movement or action—*e. g.*, table-turning and the phenomena of thought-reading are based on this fact."

Foster's Encyclopedic Medical Dictionary gives the following definition: "The act of suggesting; the thing suggested: Hypnotic suggestion; the process by which an hypnotized person is made to accept a hint or statement, although it may be unfounded, and to act accordingly."

It will be observed that both Tuke and Foster raise the point of credulity in the hypnotic state. It is this very condition of childlike faith found in hypnosis that makes that state so favorable for the presentation of suggestions. Born of our life experiences we build up in our minds certain conceptions of our body, its functions and its diseases. In most instances they are crude and imaginary, but nevertheless they are real to us. It is strange how these self-developed ideas dominate our after existence, many times to our serious physical injury. This is also true of our conceptions of our material environment, so much so that sometimes I feel like saying that the thing perceived is to the perceiver only what to him it appears to be.

In the hypnotic state these self-constituted pictures of persons including our own selves, and things are to a very great extent set aside and a childlike condition of mind established. The mind becomes, as it were, a clean sensitive plate for the reception of all concepts or ideas that are brought within the range of its vision, provided the ideas suggested do not antagonize the individual's conception of right and wrong or directly endanger his physical welfare. While it is true that we do not fully comprehend the *modus operandi* by which suggested ideas are carried out, yet we do know that physical, intellectual or moral experiences, in order to influence mental states, must find recognition within the sensorium. Otherwise they are inoperative. It is not, however, essential that they come within the grasp of consciousness, as some hold, in order that they become causal impulses. This is shown by the results of post-hypnotic suggestions that are made in the hypnotic state with total amnesia upon awakening. Such suggestions are often carried out in the waking condition after an indefinite lapse of time. Then again, we only hear a fragment of the unending song of weal and woe and catch but a passing glance at the panorama of printed matter that flows constantly from the jaws of the unnumbered printing presses, that form such important factors in our daily experience. Neither do we apparently take cognizance of the on-rushing tide of humanity that sweeps by continually, but nevertheless it all goes to make up our individual environment and has its molding influence upon our lives.

An idea, sensation or experience that once comes within the grasp of our sensorium, consciously or unconsciously, remains ever after to influence our bodily functions and actions in life. Changes in consciousness are reflected in the domain of the physical whenever the circumstances or conditions are propi-

tious for their production. Time will not permit to enter into the discussion of the modifying influences of preëxisting states of consciousness upon new perceptions; permit me to say, though, in passing, that the latest thought acquisition has to pass through the test of digestion and assimilation much as does organic matter in the physical body, before it finds its place among recognized mental states.

The intimate relationship existing between mental states and physical conditions is only to be understood by a close investigation from the standpoint of psychology. Biology, except to reveal the mechanism, has thrown very little light upon the subject, by reason of the fact that biologic processes, to a greater or less extent, annihilate the vital element in nature by the methods necessarily used in its investigation, consequently the only rational manner of approaching the subject is from the side of psycho-physics, which let us proceed to do.

Impulses arise as the result of central nervous activity that is generally sub-conscious in character, although back of this unconscious cerebration there may lie a sensorial experience. All function, conscious and unconscious alike, has its inception in the sensorium. Our personality, physiognomy and bodily form as a whole is but the visible expression of this subtle, all-pervading, central force. Tendency and desire constitute the mainspring of all function and exert an irresistible influence upon form as well. "As a man thinketh in his heart, so is he," is as literally true of the physical as it is of the moral nature. By tendency is meant the hereditary influences, both physical and mental, which undoubtedly have their direct influence upon volition.

In the main the will may be classed as an inhibitive force, and as such it serves an excellent purpose in nature by regulating desire which might otherwise run away with the organism were it not thus restrained. According to Schopenhauer,¹ "emotion and feeling are states of the will and include all conditions of apprehension from mere wishing to the intensest passion." Volition is the outward expression of desire coupled with belief in the attainability of the object desired. Motion and emotion are distinctly separate experiences, yet we find them closely related in life; in fact, the only way that emotions can rise into the realm of the conscious is through the objective or physical organism, for they are undoubtedly subjective characteristics. The intimate inter-relationship of the subjective and objective parts of man's nature forms a most intricate study over which much contention has arisen.

Ladd, with whom our investigations lead us to agree, says, in his "Philosophy of Mind:" "The dualistic theory is the popular and only justifiable metaphysics for the investigator who wishes to confine himself as closely as possible to the scientific study of either mental phenomena or the phenomena of the physical sciences. It is the only intelligible and defensible conclusion of a critical metaphysics as applied to the study of the real relations of body and mind." "The ordinary objections to the dualistic view of the real relations of body and mind have reference to certain differences in conceptions of the nature and application of the principle of causation." "On this point the opponents of dualism are wont to criticise its adherents for their view of the interaction of these two alleged

¹ Fourfold State and Will in Nature.

substances." "The word interaction may be used appropriately enough to describe under one term all relations in reality between the body and mind, if only clear and consistent conceptions as to the meaning of the word be formed and maintained."

The more radical school of evolutionary psychologists, perhaps best represented by James, of Harvard, holds to the theory of a "mind dust" and says "that if evolution is to work smoothly, consciousness in some shape must have been present at the very origin of things." While I am willing to admit the reasonableness of the latter part of the proposition, I do not see any reason for claiming a "nebular" origin for mind or intelligence upon such a premise. It would seem more rational to hold to the theory of superiority and preëxistence of intelligence, which in this instance would represent mind, and claim that it finds expression in nature, body, as an essential part of it; molding, modifying and using it to suit its own purpose, and when finally done with it casting it aside as a worn-out garment.

Individual intelligence is a matter of growth based upon personal experiences rising out of special environment. This intelligence is not a *de novo* product of highly endowed matter, because even the lowest forms of life present some degree of intelligence, but in its higher manifestations it is the outgrowth of two forces working conjointly for the upbuilding of a more perfect organism. The first principle, therefore, to be laid down as offering a working hypothesis as to the probable channel through or by which suggested ideas may be made to assume definite form in action or activity of bodily function, is to be found in the reciprocal interdependence of body and mind. We learn, as children, of our ability to perform certain acts by finding ourselves involuntarily performing them. Indifferently it may be at first, but action once born, we go on voluntarily, improving upon our first efforts until a certain degree of perfection is finally acquired. Some one has said that confidence, or faith, is born of the knowledge of having once successfully performed an act.

In the main, voluntary function is performed within the realm of consciousness, but what of so-called involuntary function? Hypnotic experience is rapidly convincing experimenters in this field of psychologic investigation that there is really no such condition as involuntary function, but that which passes for such, is only so because of the lack of knowledge of how to induce a condition of voluntary activity in any particular organ or tissue. Any attempt to discuss this phase of the question leads to the consideration of the nature of causation and the principles that underlie the inception of any given chain of movements or series of bodily functional activities, to which let us now turn our attention with the view of determining, as far as possible in the limited time at our disposal, how the mind operates upon the body in health and disease.

I have already alluded to the interdependence of mental states and bodily conditions, and indicated the fallacy of having one theory for the principle of causation of mental states and an entirely different theory for the phenomena of bodily function. We speak of the former, mental states, as being caused, influenced and determined by the latter, therefore if the law of interdependence be true we should not hesitate to speak of mental states as causative agents in determining bodily conditions, within certain lim-

itations. Favorable physical conditions are a prime necessity for the highest state of functional development. Diseased conditions of the mind invariably cause disease of the body by perversion or inhibition of normal functional activity, but it is not our intention to enter into this part of the subject any further than is necessary in order to establish the channel of action in diseased conditions and point out the probable line of procedure necessary to establish healthy function when once it has been disturbed, by calling to our aid the active coöperation of suggestion, attention and desire as dynamic forces of the mind.

Nature has beneficently arranged her plans so that all necessary function is pleasurable and, in the main, performed within the realm of unconsciousness. Whenever any function comes prominently into the field of consciousness so as to fix itself in the attention, it is in serious danger of becoming diseased. It is neither comfortable nor safe for the working of any bodily function, except under the direction of a skilled physician, to come under the influence of the attention for any considerable length of time. This danger will be more fully appreciated when it is known that attention is the offspring of the emotions and consequently embodies motor phenomena. It, attention, therefore may become a serious vital depressant or hyper-excitant, and the converse is also true, that rightly directed it may be made a powerful stimulant to increased functional activity, and thus aid in the restoration of healthy function.

Ordinarily attention is an effect and not a cause, and nature has so ordained it; otherwise it might be made to hold on to some one function (persistent idea) to the exclusion of all others, and thus act to the detriment if not the fatal injury of the organism as a whole. The highest achievement of volition conceivable is the fixing, by force of the will, a disagreeable object or function in the attention and there keeping it continuously until ideomotor impulses have arisen. In such instances the fact is plainly demonstrated that attention is an effect with motor impulses and under the control of the will of the individual. The will in this instance operates by inhibition and suggestion operating through the will tends to fix the attention on one object or set of ideas, consequently making attention its basis of operation.

Attention may be divided, for convenience of study, into two forms; natural or involuntary and educated or voluntary. The first is exhibited by all animals, man included, and is the lowest form of this force. It is the form also that has to do with most bodily functions. The second form, educated attention, is the higher of the two and to a very great extent is confined in its manifestations to educated man and a few of the domesticated animals. The power of attention is in a direct ratio to the intelligence or intellectual attainments of the individual, irrespective of genera, species or sex, and depends upon the action of the mind for its maintenance and is therefore essentially a motor phenomenon acting through the muscular system. It may become an inhibitive force when so directed by the mind as well as a progressive power. Healthy function, as we have indicated, is a pleasurable habit, or should be, and in its natural performance belongs to the realm of involuntary unconscious activity. This is shown by the bodily habits of dumb brutes and uncivilized man. In the gratification of their animal desires

and the performance of necessary bodily function these respect neither times, places nor persons. The same may be said of the infant offspring of civilized man and household pets in general. Not until they have been taught by experience do they show any sense of the fitness of things. Even in those commonest of functional activities—micturition and defecation. Necessity and the frequent calling of the attention to the ethics of the matter finally, if the individual is possessed of any degree of intelligence, places these functions on the voluntary list and brings them under the domain of voluntary attention, thus demonstrating that voluntary attention is a child of education, the product of civilization.

Now, if compulsory education can be made operative in the above instances and in many others, had we time to recount them, it stands to reason that if the means of enforcing or directing the attention could be known for each and every function, voluntary functional control in healthy organs could be established at all times and also reestablished when suspended provided the sensori-motor tracts had not been abolished by disease processes. I believe that the day is not far distant when so-called involuntary function will be superseded and that man will be able to bring all his organs under subjugation to his will. The heart and uterus have hitherto been classed as involuntary organs, but physiologic investigations in the domain of hypnosis have demonstrated that they are amenable to suggestion to a greater or less extent in susceptible subjects, and if this is true in certain cases it goes to show that if the right line of procedure were adopted, that their control might be made universal to the great advantage of the individual in the treatment and prevention of disease. The rapid advances made in the study of physiologic chemistry within the past few years has thrown much light on the nature of function, and it now remains for experimental psychology to point out the means for its control. The law of nature is in harmony with a constant tendency toward restoration when once discord or disease exists.

With all that has been said and may be said, truthfully or otherwise against psycho-therapeutics, no physical injuries can be laid to its door, which is more than can be said of any other specific line of treatment. I say specific because where it is applicable, no drug can be more certain in its results. It has its limitations just as any other therapeutic agent, and its advocates do not put forth claims for it as a "cure all," but do strongly urge its use in its proper sphere. Suggestion is a positive force and a direct causative agent in the control of functional activity and a most useful therapeutic agent in the restoration of healthy function when once it has been disturbed by any cause, except wasting disease that has destroyed the organ itself, in which case no agent can do more than relieve the distress, and in this phase of treatment suggestion stands without a rival. Beginning as an empirical practice, even as more material medicine did, in many instances psycho-therapeutics is rapidly reaching a scientific basis in Europe and to some extent in this country. It has been my good fortune to have had the opportunity to look into the methods of its advocates abroad to a considerable extent and I have become fully convinced of its efficacy in the treatment of certain pathologic conditions. It is true that up to the present these have been

largely in the nature of neuroses, but with the rapid advance in our knowledge of the nature of function through researches in physiologic chemistry and experimental psychology I look forward to a much wider field of usefulness for this natural remedy of perverted function. Let me therefore for a few moments call your attention to the probable line of its application.

As we have before seen, all function has its inception in the sensorium and any derangement in this center, either functional or organic, is liable to find expression in disordered functional activity. Diseased mental states, however, are much more common than we are wont to think, because they do not show as such directly but are often times reflected in different parts of the system. The emotions, fear, grief, anger and hate have long been known as having a marked effect upon the human barometer and should receive careful consideration at the hand of the general practitioner. Fear is especially most subtle and lasting in its influence. Many cases might be cited where fatal results have been produced through fright, and on the other hand, joy is also said at times to kill. The quickest way to effect cures in bodily ailments arising from emotional causes is to go directly to the seat of the disease, the mind, and disabuse it of its hallucinations by appealing to its understanding rather than to the organs, which only reflect the central disease. It is generally well to treat urgent symptoms from the standpoint of general therapeutics because most patients have been brought up with the material idea of the potency of drugs, consequently the strongest suggestion that can be made under such circumstances is the administration of some medicament with the action of which he is more or less familiar, the idea being to create the quickest and firmest mental impression possible. But every physical suggestion, even if it is only in the nature of a placebo, should be accompanied by verbal suggestions. Many a case has been relieved by similar lines of treatment and a permanent cure established by continued suggestion directed toward the restoration of healthy function. There is hardly a diseased functional condition to which the human body is prone that may not be directly benefited, if not permanently cured, by the aid of suggestive therapeutics; not only this but many organic lesions are improved, indirectly, by controlling the vascular supply and inhibiting destructive metabolism until vital processes may be restored.

Pain may be thus inhibited, a fever lowered and the pulse controlled. Nervous dyspepsia is often permanently cured. Also neuropathic affections, including hysteria, insomnia and paralysis, have been cured. The various forms of nervous prostration are specially amenable to treatment by suggestion. Chorea is easily handled; epilepsy controlled as by nothing else and dysmenorrhea cured. Organic diseases of the nervous system are improved indirectly by relieving the reflex symptoms and thus doing away with the strain upon the organism as a whole. Stammering, in cases where there are no physical lesions, which are seldom found, readily succumb to suggestion. The extended field of reflex neuroses are benefited by suggestion and nearly all the disagreeable symptoms of rheumatic affections relieved. Alcoholic and other forms of inebriety, including tobacco and other vicious bodily habits in general, are successfully treated in most all cases. Perver-

sions of the sexual instinct are most happily handled by suggestion. Melancholia and paranoia in general form a fruitful field for its application.

Suggestion may be administered in the waking state, but the happiest manner of presenting it is in the hypnotic state, because in that state there exists the special form of passivity which is most conducive to the highest receptivity of suggestion. After a patient has been hypnotized several times this method is dispensed with and suggestions made in the waking state. By reason of the fact that the subjective mind is incapable of inductive reasoning, it is necessary that the successive steps to be pursued in the treatment of any given case should be specifically outlined at the beginning of each sitting in order that the best results may be attained. This rule is equally applicable to suggestive treatment in the waking state, as such methods are based on pure psychologic grounds and tend to secure the greatest degree of confidence in the line of treatment adopted and best operates to secure the establishment of ideo-motor and ideo-dynamic impulses in the restoration of healthy function.

The phenomena of perverted functional activity have long been before us, the fullest application of the cure is yet to be made, for as yet we have only caught a glimpse of the boundless possibilities of suggestive therapeutics coupled with a judicious use of specific drugs. Bernheim says: "It is a physiologic law, that sleep puts the brain into such psychic condition that the imagination does accept and recognize as real the impressions transmitted to it. To provoke this special psychic condition by means of hypnotism and cultivate the suggestibility thus artificially increased with the aim of cure or relief, is the rôle of the psycho-therapeutics." Couple with this a careful scientific explanation of the functions of the disordered part and the specific line of action of any drug in aiding nature in the cure of the condition, and an ideal line of treatment is established. While suggestive therapeutics is not a new subject, it has only within the past few years been placed upon anything like a scientific basis. With the advance in our knowledge regarding the physiology of function through physiologic chemistry and psychology we are becoming better prepared to direct it. The power of the imagination has long been called upon to assist in the cure of diseased conditions. Lack of knowledge as to how the special functions of the body produce results has prevented the intelligent use of this agent in the past. History is, however, full of the miraculous cures of all manner of disorders. The strong hold that faith cure and Christian science have gotten upon the people, witnesses the power of suggestion in the treatment of disease.

Suggestive therapeutics, like all other lines of treatment, has its limitations, else final dissolution could be abolished. The first limit is lack of faith in the complete efficacy of the remedy. We stop short of success in many things in life by reason of our inability to persist to a finish. This is not always the result of lack of faith, but is, many times, a physical defect. Poor human nature becomes exhausted, and we give up the ghost, literally as well as figuratively. There is a limit to the resistive quality of protoplasm just as positively as there is a point where cohesion in the molecules of metals fails, and yet it goes without dispute that

the will has saved the life of many a man by carrying him over the crisis. Physicians all recognize it in the treatment of disease.

In conclusion, I desire to say that I am a firm believer in the value of suggestion in medical practice, and that experience, based upon years of scientific study in the phenomena of function, leads me to earnestly advocate the use of hypnotic suggestion alone in the treatment certain forms of disease and its general use as an adjunct to already accepted therapeutic measures.

100 State Street.

A SIMPLE METHOD OF DRESSING FRACTURES OF THE EXTREMITIES. AN AUXILIARY TO THE BANDAGE.

Read in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY JOHN EPH. LINK, M.D.

TERRE HAUTE, IND.

My object in this paper with demonstration, is to present a simple, effective and convenient method of dressing injuries of the extremities, especially the lower, whether of fracture as the paper is headed or dislocations, sprains or contusions and lacerations of muscle or tendon, everything indicating rest of tissue; a dressing embracing the principle of rest without restraint; a simple auxiliary to the bandage.

I hope to be able to demonstrate at some future time that all progressive tendency to displacement from reflex irritation can be avoided by placing the muscles in a state of rest by simply encasing the limb in an easy environment.

The bandage of old, well worn muslin in successive layers comes as near meeting these indications as any other and with nack can be made almost, if not quite, as effective in soft even cushioning as with the cotton batting and much more retaining.

The device that I have adopted is the thin shavings of birch wood used in commerce for packing tubs and buckets, which I here present; and as you will, I think, readily comprehend enables one to lay the bandage equally as smoothly and is a safe-guard, against their being easily displaced; a most desirable consideration where it is so desirable, as in cases of fracture, to maintain the parts in a fixed position for a considerable length of time. The advantage of this over the plaster dressing is two-fold, first, ventilation, the admitting of free air and free exhalation from the body, as we have markedly here the advantage in irrigation and washing of limb and dressings without removing the covering. The bandage and splints are susceptible of being washed clean from all fouling of secretions; even the skin made so in bathing through the covering either with hot or cold water, as may be preferred, in a few minutes time, by continuous irrigation. After a thirty minutes' washing the dressing will again dry in a little longer time, say in one hour. The special advantage that I have found in the use of the shavings of wood over zinc tin, is that there is just sufficient roughness in their surfaces to make a firm cohesion with the bandage when applied wet, and more or less pliable alike whether wet or dry, and in their extreme thinness, easily fitted, by fraying, to the irregularities of the limb, protuberances and depressions.

You will notice in the illustration I present you that the spreading is easy and graceful, fitting over the enlargements and that the overlapping at points of narrowing is not bungling; and further with a pair of blunt scissors which you may carry in your vest pockets, the parts of segments can be clipped away so as to avoid even this small amount or irregular thickening if desired, and at the same time not interfere with the utility of the splint, and as layer after layer can be sandwiched with the consecutive layers of the bandage we can easily so shift the pieces as to compensate in the one for the deficit of the other, and when after the limb is once so environed we have lightness and strength combined a perfect retention with a minimum part of cumbersome restraint to the injured tissue. There will be also a lack of the feeling of arbitrary force as in the more cumbersome dressing and, as I think you will at once comprehend, a better physiologic reparative condition.

Excuse me, if I here may seem to impose upon your time and patience in suggesting a further thought,

As applied on an artificial limb for demonstration before the session.

that with the interwoven splint and lines of the roller bandage circular, diagonal and longitudinal, up and down the axis of the limb, that the changing of any part of your dressing to the extent of weakening the support or adding to the discomfort of the patient by pulling in cords drawing or pressing from thickening, as is liable to be the case in the cotton under the plaster, or of the plain roller bandage, without stiffening. You will find after weeks of wearing of the shavings that your dressing, bandage and everything else is as smooth and perfect as the hour you first adjusted it.

My experience in observation is that there will be, in no instance, that stiffness of joint or shrinkage in the muscles as is apt to be the case with the more stiff and arbitrary enveloping of the limb, as in plaster or silicate dressings. There will be, at no time, during the time of applying this dressing any danger

of losing the proper control of the injured member, as from sudden stiffening nor delay of hardening, as in the use of plaster of paris.

The nature of the stiffening from non-friableness and cohesiveness of the wood and muslin as above, is such that if timely looked to can be changed a little here or there, more or less. You will, I have no doubt, be surprised to learn, in some of these efforts at changing, and appreciate the firmness with which even a small piece or mere splinter, it may be, will remain in its place and thus be assured of the reliability of the method. When you have finished with a few layers completely surrounding the limb, you can lift it with impunity, changing from place to place with the least danger of displacement of the fragment and a minimum of discomfort to your patient. I can only assure you that I have frequently dressed a compound fracture of the leg with loss of substance of tibia and fibula of several inches, with perfect results in the normal line and length. The parts were kept healthy and clean by irrigation or washing for weeks, and until repair was perfect, without changing.

ASEPSIS AND ANTISEPSIS IN OTOTOLOGY.

BY J. HOLINGER, M.D.

CHICAGO.

The application of the principles of asepsis in all their details has brought great progress in general surgery, in hygiene and in the particular branches of gynecology, obstetrics and ophthalmology; but in some other departments of medicine much is still to be done, before the ideal condition desired by the friends of asepsis will have been attained. Among these latter it seems to me that otology must be included, and that as regards it, the greatest number of scientists underrate the value and misunderstand the necessity for the strictest asepsis. Of course in large operations the instruments are boiled, the patient is cleaned, and as a rule the operator's hands are more or less carefully disinfected. But between this and a complete, consistent and thorough asepsis there is a wide difference. The principles of asepsis should be carried out in otology in the routine examinations of the ear, and especially in the seemingly unimportant details of ambulatory practice. A little reflection will show that hardly anywhere is strict asepsis of more value than in ambulatory practice. Except in cases of very small children we have to use instruments in every examination, and to use them in parts of the body normally covered by only a very tender epidermis, parts that are not accustomed to nor able to endure irritations and that hence are extremely vulnerable. Furthermore, there is no physician who comes so much into contact with putrid and virulently infective material as the otologist. Yet it must be admitted that there are many otologists who do not acknowledge the necessity of asepsis in their department. Their view is not based upon the absence of ill results in their cases, because such results do exist though they are not always readily recognizable and their recognition demands an experienced eye. Even when recognized, there is often lacking in those who are responsible for them the courage to admit them either in public or in private. If a confinement case be managed improperly and uncleanly, the evidences of infection will appear within a few days at the very spot where it occurred

and a violent form of sickness results. In that case there are hundreds of widely open lymph channels to carry the infection into the blood; but in diseases of the ear the avenue of infection is less apparent and the process is slower, since it takes place through minute openings in the bone. A violence done to any soft part with an infected instrument will show its effects at the very spot within a few days in the form of an acute inflammation, but in otology the place, the time, the manner, the where, when and how of infection are entirely different from what we expect. This is proved by a few examples. Who would expect an erysipelas of the face to originate in a minute injury made by an unclean Eustachian catheter on the mucous membrane far back in the nose? Yet precisely such cases are not infrequent. Again, it would seem hardly possible that a middle ear suppuration of twenty years' standing and ending in necrosis, cholesteatoma, deafness, cerebral abscess and death should have been due to the use twenty years earlier of an unclean ear speculum or probe used by a doctor, or of a hairpin used by a mother in cleaning her baby's ear. Yet such is the origin and history of cases that occur not infrequently in practice. The explanation becomes clear to any one who will follow up the results of bacteriologic examination of aural secretions. It has been established by the independent researches of many investigators that the pus of acute otorrheas contains as a rule only one species of bacilli or cocci and only exceptionally any streptococci; whereas in chronic cases these latter are usually present. In other words, *acute infections of the ear are due to a single species of microorganism and heal quickly; while chronic otorrhea is due to a mixed infection with streptococci.* Hence the force of the old saying: "As soon as you treat (with non-sterilized instruments) an acute suppuration of the ear, it becomes chronic." No more apt vehicle for mixed infection can be conceived than an ear speculum if it is not properly disinfected, for when used in a suppurating ear its lumen is certainly soiled by the pus and when applied to the next patient's ear the infectious material is carried inward by the probe and cotton. Thus a chronic otitis is generated which insidiously destroys hearing, and perhaps after the lapse of years even imperils the victim's life. Not less frequent is infection of the soft parts of the external meatus through imperceptible and scarcely avoidable excoriations made by unclean specula. Sometimes the whole meatus is filled with pus, and this a careless examiner may press into and massage into the tissues. The infection will manifest itself either in the form of a general inflammation of the auditory canal or in a local furunculosis. It will not endanger life nor will it last for years, but it causes much pain, and by depriving the patient of sleep and appetite may injure him seriously.

Beside these forms of infection which remain localized, unclean aural instrumentation may be also a means of introducing chronic general poisons, such as those of tuberculosis and syphilis. Many otorrheas are tuberculous, and they may be so without there being any other tuberculous affection present in any part of the patient's body. Cases are recorded of general miliary tuberculosis following a tubercular osteitis of the temporal bone. In the case of syphilis, the sequence can be traced out more directly and more surely. A number of cases have been published of syphilitic primary lesions within the nose

and doubtless many more have not been published or have escaped observation. The statement may seem exaggerated, but I believe that it furnishes an explanation for some obscure cases of syphilis without any visible scar of a primary infection on the whole body. Some practitioners may shake their heads and smile at these views and go along in their old dirty ways. So did others when Pasteur and Lister published their principles and results. Time will prove the right. Certain I am that when legislation deals fully with the permissible and the criminal acts of physicians, it will devote a chapter to avoidable infections.

Antiseptic solutions, such as carbolic acid, etc., are generally not thorough enough for disinfection. They serve rather to lull our consciences. Therefore I would state the following practical rules for aural work:

1. Every instrument should be so constructed that it can be easily cleaned and examined.

2. Before every examination the instruments (speculum, probe, catheter, middle ear instruments) should be sufficiently boiled, and immediately after use they should be washed in cold water, so that the pus, mucus and blood may not coagulate and dry on them. Of course, it goes without saying that the hands must be kept clean according to the general rules of asepsis.

A recent article mentions a handy way of sterilizing the cotton. After being attached to the probe it is dipped into an alcoholic solution of boric acid, and then held in a flame till the alcohol is burned out, the boric acid preserving the cotton from burning.

The carrying out of these principles involves much trouble, time and expense, but they should not be spared in private and especially in *dispensary practice*, where so many cases, chronic, acute, specific, etc., pass through a rapid examination. The benefit may not be expressed in numbers, but it exists and is worth attaining.

HOW TO SECURE ASEPTIC LABOR.¹

BY DOWLING BENJAMIN, M.D.

CAMDEN, N. J.

It was a bright day for women when the leaders of scientific investigation in the medical profession announced this discovery that the infectious fevers were caused by minute organisms, called germs or pathogenic bacilli; for it was only by the discovery of the cause of child-bed fever that we were enabled to prevent its occurrence.

To show the importance of this subject I may simply quote you a few figures. Taking New York alone, from 1886 to 1887 there were 3,342 deaths incident to child bearing. Of these deaths 1,947 were due to child-bed fever, or the infection to the lying-in period. (See Pepper's System of Medicine, vol. 1.)

Fully half of the deaths, therefore, that occur at the confinement period are due to infection, septicemia, pyemia and from blood poisoning, caused by fever germs getting into the system through the abrasions caused by parturition. And you must also remember that aside from any other lesion, there is always after every confinement a large, raw surface left on the interior of the womb by the separation of the afterbirth, which is one of the most dangerous fields for the growth of diseased germs and their ready entrance into the woman's system.

¹ Extract from a lecture by Dr. D. Benjamin, Obstetrician at Cooper Hospital.

For the proper and successful care, therefore, of a mother at this important period of her life, it is of the greatest importance that you not only understand but apply the principles of asepsis. Since the alert members of the profession have thoroughly comprehended the importance of this subject, child-bed fever has been so rapidly diminished in frequency as to arouse the hope of making a case a rare curiosity.

My own experience in this matter, during a practice of nearly twenty years, in which I have endeavored to apply the principles of antiseptic practice, has been that I have had but one case of puerperal fever and that fortunately recovered.

How then shall we proceed to secure our patient against the dangers of sepsis?

Call upon your patient at least once after having been engaged and explain to her the importance of this subject and, as well as you can, briefly the principles involved. Then direct her to make the following preparations:

1. Keep clear, if possible, from all contagious and infectious diseases.

2. Avoid sores (wounds included) and especially erysipelas.

3. Warn her to advise you of any abnormal symptoms, such as headache, dizzy spells, swelled feet, etc., which might presage albuminuria or other dangers.

4. Tell her to have on hand as soon as the first symptoms of labor begin, or before if possible, two or three gallons of sterilized water (either boiled or distilled) in a sterilized boiler or pitcher, properly covered from the dust. This sterilized water must not be cooled by adding cold, unsterilized water, a thing that unskilled attendants will be very apt to do unless you watch them. Even the baths that a patient takes before or after confinement should be in sterilized water, or at least aseptic water, and since many cities take their water supply from streams in which their sewage is emptied this is difficult to do unless the infected water be boiled. You actually infect patients who might be aseptic by giving them a bath in such water as is supplied to many of our cities.

5. All water used in the lying-in room must be sterilized. Also the hands, or anything, can be washed much cleaner in a stream that is being poured from a pitcher, than if they are dipped into a basin containing the dirty water in which they have been washed, even though no discoloration can be seen in the water.

6. Everything to be used about the patient and bed in the way of clothing, etc., must be washed, boiled and ironed, wrapped up from the dust in a paper and put away to be ready for use when the time comes. (The conditions present and the antiseptic preparations are essentially the same as you would expect to have in a great surgical operation.)

7. She must have at least one dozen aseptic pieces of muslin, about fifteen inches square, boiled, washed and ironed (an old sheet torn up will do), wrapped up in paper and put away to be used for wiping away the discharges, for wash-rags, napkins, etc.

8. One large pad about one yard and a half square, made of cheese cloth that has been boiled in water containing a small quantity of soda and stuffed with new cotton, or what is better, absorbent cotton. If ordinary cotton is used it will have to be baked for an hour to secure sterilization. About a pound and

a half of cotton will be enough, although two pounds would not be too much. This is to place under the patient during confinement, first, second and third stage, and must be removed soon after the first stage to be replaced by a lighter one, also sterilized. Everything if the least bit soiled must be removed from the patient, bed and child promptly, lest culture-fields be formed for germs.

9. One sheet of impervious cloth, about a yard and a half square, to be put next to the mattress for its protection.

10. One maternity binder, about eighteen inches wide and long enough to go around the patient, sterilized.

11. One piece of sterilized soap (hydronaphthol) or carbolized.

12. One new sterilized syringe, "Household No. 3" or "Fountain" will do.

13. Two-ounce box of antiseptic cosmoline or sweet oil.

14. One skein of sterilized silk floss.

This much preparation I have always been in the habit of ordering my patients to make and is in the reach of those in the most ordinary means. These things should all be wrapped up properly from the dust, so that they may all be found without confusion when the time comes. For a complete and perfect outfit which could be inclosed in one neat box, I would suggest the following. Though a little more expensive, it should be gotten up by a manufacturer of antiseptic supplies, put up in a neat package, and would be a great convenience to patient, nurse and doctor.² Nay, I feel warranted in going further, and stating that the adoption generally of the practice herein suggested and urged will introduce an era in obstetrical practice marked by a lower death-rate than that of any preceding period of practice.

THE BENJAMIN MATERNITY OUTFIT OR OBSTETRIC ANTISEPTIC CASE.

1. Two aseptic sponges.
2. One card No. 14 sterilized silk.
3. One-half ounce of salicylated cotton.
4. One half-curved needle.
5. One-half dozen sterilized safety pins.
6. One dozen aseptic cloths about fifteen inches square.
7. One dozen antiseptic absorbent pads.
8. One large aseptic absorbent pad one and one-half yards square.
9. One maternal binder, sterilized.
10. One cake sterilized soap.
11. One jar sterilized petrolatum.
12. One sterilized Fountain syringe.
13. Two clinical charts (Wilson's) for mother and child.
14. One obstetric chart and report (Benjamin's).
15. One impervious sheet, a yard and a half square.

The articles in this collection to be used as follows: The aseptic sponges may be used to cleanse lacerated or bruised surfaces in mother or infant.

The sterilized silk to be used for tying the cord, and together with the surgeon's needle may be used to stitch up any lesion of the perineum, and may sometimes save the patient and the doctor a great deal of trouble.

The salicylated cotton will be used to apply to the navel.

² If placed upon the market.

The needle for any lacerations that may occur during the parturition.

The safety pins may be used for the maternal binder, and also for the child.

The aseptic cloths are to be used to absorb discharges during all stages of labor and for washing purposes, and for tampons if need be.

The antiseptic absorbent pads, one and one-half yards square, are placed immediately under the patient or under the sheet which has been sterilized by boiling and ironing for the occasion, and may be pinned or tacked to the sheet or to the impervious mackintosh beneath.

The maternal binder to be placed around the patient after delivery in the usual manner.

The sterilized soap, made especially from pure castile and imbued with naphthol and boracic acid, is used for all the ordinary purposes of the soap, and is perhaps one of the best combinations that can be used for ordinary purposes.

The sterilized petrolatum is used in the place of lard, which on account of its dangerous impurities should not be allowed in the lying-in room.

The sterilized Fountain syringe is to be used for ante-partum and post-partum, vaginal or uterine douches.

The clinical charts should always be started at the beginning of labor, if not before, for the mother, and for the child as soon as practicable after birth.

The obstetric chart and report gives the physician not only a good record of the case, but the information necessary for making his official report to the public authorities. It can be filled up by the nurse at her leisure and will save the physician much of the usual delay in obtaining the necessary information.

The impervious sheet, one and one-half yards square, is made of gum cloth and is to be placed next to the mattress for its protection and under the large absorbent pad and sheet, to which it may be pinned or tacked, and after the confinement is over will be found exceedingly useful to spread under the infant to protect the mattress. In cool weather it should be placed under the sheet.

We might add to this outfit to make it more complete, one dozen of corrosive sublimate tablets, containing seven and three-tenths grains each, so that the nurse and physician may sterilize their hands before touching the patient or the outfit. One dissolved in a quart of warm water makes a solution of 1 to 1,000.

Caution.—As they are exceedingly poisonous their use must be accompanied with great care and strictly in accordance with the instructions of the attending physician. They must be kept out of the way of children, and solutions made from them carefully guarded and thrown away as soon as use is finished, to prevent being mistaken for drinking water. These solutions of corrosive sublimate must not be kept in any vessel used for drinking purposes.

And we might also add as the seventeenth item one ounce of saturated solution of boracic acid, with which the baby's eyes should be thoroughly washed out immediately after delivery.

The foregoing I have designed especially for private practice.³ In the maternity department of the Cooper

Hospital, which is under my charge, some slight modifications I have necessarily made in this outfit so as to adapt it to hospital use. By this careful preparation and its proper use we will generally be able to avoid that unfortunate and fatal affliction of motherhood, puerperal fever. In the lying-in room the nurse should be the picture of neatness, cleanliness and pattern of aseptic practice.

What a contrast to this preparation and picture which I have just presented to you, is the situation a physician so often meets with; too often.

The following is the form of the obstetric chart and report:

OBSTETRIC CHART AND REPORT.

SCIENTIFIC CHARITY.

Read at the meeting of the Physicians' Club, Dec. 30, 1895.

BY BAYARD HOLMES, B.S., M.D.

PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS. CHICAGO.

There are two distinct ideas pictured by the word charity, and the notions which these ideas convey have little intrinsically in common. In one sense charity stands for fellowship, fraternity, good will, love, human sympathy and justice. In this sense charity is good and will always be of unexceptional application. It is in this sense that Paul and Portia used it in those well-known and much-abused paragraphs.

In its second sense, charity embraces all those ideas represented by alms, almsgiving and all those institutions, organizations and systems employed in giving gratuitous relief to the poor. It is in this latter sense alone that charity is used by me in this discussion.

In this sense there can be but a limited application of the terms scientific charity. Scientific charity is really no charity at all, because science and reason direct all the energies of society not to the alleviation of the suffering of the poor, but to the prevention of poverty. Science insists upon the fact which true humanity has always believed, namely, the ability of the earth and man's labor to produce enough and more

³ I have been of late in the habit of ordering such of my patients as could do so, to purchase it at the antiseptic supply stores, put up according to the above directions.

than enough for all. Therefore there need be no poor. There should be no almsgiving. Still the fact remains. Poverty and nakedness and hunger are present in spite of too much wheat and corn, too much coal and oil, too much wool and cotton, too much lumber and iron, too much labor and machinery, too much power and too many labor-saving inventions. In fact just as the products of the earth, of the hands of men, of machinery and of the devices of genius multiply, just in that proportion does poverty, idleness and wealth increase. And since the poor are with us almsgiving is necessary, just as much so as calking is necessary to the ill-built ship. It is perhaps worth while to inquire into the source of the various groups that demand alms.

The first to receive gratuitous aid and support are the very old and the very young. At both ends of life man must depend upon the product of others' labor and the services of others for support and comfort, and this seems reasonable and just. This helplessness of the old and young seems to be the foundation motive of the family unit. Only rarely is the community called upon to care for the old or young except on the dissolution of the family unit to which they originally belonged. When the maintenance of the family unit is not guarded by the community then this group of dependents increases. Some one may ask how scientific charity directs alms to be given to this group. In this as in many other public matters Australia has given the best answer. That is a country without an orphan, without an orphan asylum and without an old people's home. All the dependent babies, children, old women and old men are adopted by the community, and with proper supervision they are boarded out in homes in the colonies where their presence is welcome, where they have the cheer and the comfort and love of home life. In these homes, too, the young are prepared for a useful manhood and womanhood. Scientific charity blushes at the sight of the imposing architecture of the orphan asylum and the old ladies' home no less than at five thousand homeless children on the streets of Chicago.

The second to demand alms are those who suffer from disease, from injury or from mental or physical defects. As medical men we are most interested in this group, and naturally they are our special care. As physicians and surgeons we attend the sick gratuitously in all public hospitals. No other profession gives so valuable a public service without pay. But we rarely consider the motive which most promotes that symptom of social disease known as hospitalism. This mania for hospital building breaks out wherever injustice and oppression most prevails. When the severities of feudalism pressed hard upon the people, Europe was dotted with hospitals. Now that commercialism and capitalism are crushing all manliness out of Americans, hospitals are filling the land. The real motives of hospital building are these: To furnish a place into which to shove off unwelcome servants, friends and relatives when they are sick; to furnish a means of altruistic activity for women who suffer from this constant exercise of the cruelty, inhumanity and injustice of modern society, and to help the employer to beat down the wages of his men. If an employer is obliged to pay for labor a dollar a day before a hospital is built in his community, he can cut down that amount an appreciable per cent. as soon as an institution is established. Hospitals and dispensaries lower the standard of life in a community in

which they are built and the medical man who serves in hospitals without pay is taking the bread from the mouths of professional brethren and doing the laboring classes the greatest injustice. It is obnoxious to the high ideals of our profession to suppose for a moment that any true physician coöperates with spread of hospitalism, knowing its real significance. Yet there is a growing class of physicians who look with equal disfavor upon the professional hospital builder and the professional hospital physician. The one works on a commission of 20 per cent. of all he can get out of the rich and the other takes all he can detract from the physicians who endure the heat and burden of the day.

It is often said "capital takes all the risk" but with the growth of machinery this adage must give way. In the United States in 1892 there were 821,000 men employed on railways and 2,500 of them were killed outright, and 28,000 injured. These injured men and their families demand alms largely because men are cheaper than better material equipment. The one can be had for a dollar or two a day, the other requires interest and a sinking fund.

The deaf and blind furnish shining examples of the defectives who require alms. Three million dollars were expended from the public purse for the care and education of these unfortunates in the year 1892. It is the opinion of all experts who have spoken on this point that more than three-fourths of this blindness and deafness could be prevented by a better medical education and a better medical supervision and yet while the general government alone spends three-quarters of a million a year in study of the diseases of swine, not one-tenth this sum is expended by all the States together in teaching medicine, not to say in medical research.

In the third class come those who demand alms, not because they are infirm, defective or diseased; not because they are unable or unwilling to work and produce but because all opportunity of productive industry is denied them. This is the great group shut out from work because they have committed the unpardonable crime of producing too much—the great army of the unemployed. This group out-numbers many times all the others put together. The benevolent employer of labor smiles with satisfaction when he is called upon for a contribution from his private purse to carry these fellow citizens over a hard season of idleness. He knows they are the most efficient instrument of beating down wages, of lowering the standard of life, and teaching all labor the arts of thrift.

He contributes gladly from his own or better from the public purse and immediately figures on a 10 per cent. reduction of wages and a great increase in his donation to the Armenian Mission or the home for orphaned cripples. That there should be such a condition of affairs as this in a country with over-production of all that is good to eat and wear and enjoy is a sad commentary on a hundred years of American democracy. Almsgiving to this group only poultices the sore which is eating the heart out of our country, and fast reducing us to the conditions of France a hundred years ago.

In the fourth group come those for alms who find charity pays better than any profession or trade into which they can gain access. Here we find the men and women who make begging a business and conduct their affairs on the same principles that govern

all successful business now-a-days. They do not stop begging when they get enough to supply the necessities, decencies and even luxuries of life. They go right on begging and begging and begging as long as it pays better to beg than to do anything else. They are not in business for their health nor are they doing a missionary business. They are there to win.

All that one can say for this group is that they are perfectly practical and consistent. To be sure they are not reformers. They simply take things as they are.

In conclusion, let me make the following epitome: Charity, almsgiving, is an opiate now much used in treating humanity for that fell disease of which it suffers. This disease is known as competitive production. The three humors of this disease are rent, interest and profit. These humors are produced by a parasite known as special privilege. When the disease reaches its height, it is manifested by a bluish of idleness, poverty and misery which is soon followed by an eruption of benevolent societies, asylums, institutions, hospitals, dispensaries, jails and penitentiaries. In the treatment of this disease narcotics are dangerous. Almsgiving, suppression of facts and refusal to investigate have all proved fatal. These and all other methods of symptomatic treatment should be removed and the parasite should be attacked with the sharp edge, rational justice.

BACTERIOLOGIC RESULTS FROM MECHANICAL FILTRATION.

[Abstracts from a Report made by E. B. Weston, C. E., of Providence, R. I., upon Experiments made by Natural Filtration and in the use of the Morison Filter for Period of Nine Months.]

Read at the Meeting of the American Public Health Association, Denver, Colo., October, 1895.

BY GARDNER T. SWARTS, M.D.

SECRETARY OF STATE BOARD OF HEALTH, RHODE ISLAND.
PROVIDENCE, R. I.

At the last meeting of this association at Montreal the statement was made in the report of the committee on water supplies that no data had been available to show that filtration by the so-called mechanical methods was successful in removing bacteria. The writer at that time referred to experiments which had been made in the city of Providence, R. I., in order to determine this question for the purpose of establishing a plant capable of filtering 15,000,000 gallons daily if the experiments were successful.

The figures showing these results were not at that time available, and as they have never been published and as no experiments of a similar character have been made, it seems desirable to place these facts before the Association, inasmuch as many municipalities are agitated over the advisability of introducing the so-called natural or sand-bed filtration or mechanical filtration.

The mechanical form of filter used in the experiments was of the type in which quartz or sand is used as a supporting bed to a film of precipitated coagulant or fixative of organic matter, produced by the introduction into the water, before filtering, of some chemical such as iron or alum; a filter which is also cleansed by means of a reversed current of the water passed through the filter assisted by the use of a rake made to revolve in the bed of the quartz while the washing is being done.

The filters used in this line of experiments were two of the natural sand-bed form imitating the usual

filter bed. The mechanical form was represented by one of the New York Filter Company's filters and one of the so-called Morison filters. After the first seven months the sand filters were discontinued, it having been satisfactorily ascertained that the length of run was much less than the mechanical filter before the bed became clogged and the rate of flow in the natural bed was but 30,000,000 gallons per acre in twenty-four hours, while the mechanical filter was run at the rate of 125,000,000 gallons per acre in twenty-four hours. The efficiency of removal of bacteria was not as high, and the results variable, either as the result of cracks in the filter or from some unknown reason. Although both of these natural filtration beds were constructed exactly alike, the results from the second were much poorer than the first. When the natural bed was transformed or assisted by the addition of alum, thus converting it into a mechanical filter, the removal of bacteria was increased to nearly the same as on the Morison filter, but the length of the run was correspondingly decreased.

The sand used in the natural beds was a natural river sand, not over sharp, while the sand used in the mechanical filter was crushed quartz having sharp edges.

In the beginning of the experiments the New York filter gave such varied and unreliable results that its use was abandoned, while the so-called Morison filter was continued in use during the whole series of experiments, which lasted for a period of about ten months, the working of the mechanical parts of the filter being perfectly satisfactory and the results obtained being successful.

The filter bed used in this mechanical filter was two feet ten inches in depth, supported upon a base of iron with circular perforations of about 4 inches in size, which were covered with screens. The crushed quartz used was the "effective size" of 0.59 millimeters. The filter was washed by a reverse current which caused the quartz to boil. The agitation and friction of the particles were increased by means of a rake with long teeth which revolved about a central column in the filter; the rake penetrating the bed by a screw motion from top to bottom.

From the various kinds of coagulant or precipitant used basic sulphate of alumina was selected as being the most satisfactory and effective and was used in all the experiments mentioned. The amount of alumina used was $\frac{1}{2}$ grain to the gallon of water filtered, a lesser quantity failing to satisfactorily remove the organisms, while the amount of $\frac{3}{4}$ or one grain per gallon did not increase the removal of the bacteria, while the efficiency of the filter was greatly decreased by reducing the amount of the flow through the filter bed.

The alumina was applied in a free flow at the beginning of a run by pouring into the filter, as the water entered, a pint of the coagulant containing about 911 grains of sulphate of alumina for an average flow of 128,000,000 gallons per acre. The solution was made by adding one part of the alumina to six parts of water; as a result of this addition there forms a white flocculent precipitate over the surface of the grains of quartz and is the actual medium through which the filtration takes place, the quartz serving merely as a supporting bed or sieve. It required about six minutes to form this layer. When applied at the rate of a drop at a

time and not in a "free flow" it required about a half an hour before the filtering layer would be formed. As soon as the filtering layer was formed the alum solution was dropped in continuously during the run from a regular stop at the rate of a drop a second. The effect of the presence of this layer was to reduce the head or pressure .28 of a foot for 128,000,000 gallons per acre. The depth of the water above the bed at the commencement of the run was nine inches; the average length of the run was about eighteen hours.

Under these conditions it was determined how long after the commencement of the run the filtering ability was at a maximum and also the capacity of the filtering media to remove organisms and also the possibility of removing organisms foreign to river water and simulating pathogenic bacteria in their life history. In this last experiment the Cruikshank bacillus and the bacillus prodigiosus were used, since from their pathogenic properties they could be readily distinguished from the water bacteria.

For an understanding of the proportion of bacteria found in the applied water and the number to be found in the filter water, table No. 3 of the report is here appended.

As a result of the whole series of experiments the totals shown in table No. 9 will give an idea of the averages. In consideration of this table it must be remembered that the introduction of only one result, which may be far below the average, will readily reduce what would otherwise be a most favorable average, to a lower point. This one result might occur from a temporary contamination of the effluent pipes at the time of collecting the sample, and which might not represent the exact results of filtration.

TABLE NO. 3.—FILTRATION EXPERIMENTS.—MORISON'S FILTER.

Growth of about ninety hours, of water bacteria in the sample of applied and filtered water, which were taken at the same hour; which was one hour or more after the water commenced to flow from the filter.

Date.	Gallons of Water Filtered per acre per Twenty-four Hours.	Bacteria per Cubic Centimeter.		Per Cent. of the Applied Bacteria Removed.	Average Percentage of the Applied Bacteria Removed.	Grains of Sulphate of Alumina Added.
		In Applied Water.	In Filtered Water.

During the application of the cultures of bacillus prodigiosus in large quantities suspended in the nutrient media, the numbers of the common water bacteria materially increased in the effluent, the particles of quartz becoming covered with a slimy brownish deposit. Unsuccessful efforts were made to cleanse the quartz of this growth by steaming and boiling the quartz for one hour. Finally on the application of a solution of one pint of caustic soda to twenty-four parts of water and steaming, the normal white color of the quartz returned. The efficiency of the filter was raised by this process of cleansing from 92.8 per cent. to 98.8 per cent. As to the mooted dangers attending the use of alum in the applied water and which is held up as a warning by the opponents of mechanical filtration, this much may be said in reference to this series of experiments:

While it was necessary to add half a grain of sulphate of alumina per gallon of water filtered in order to obtain the most satisfactory results, yet upon comparison by the most careful chemical tests of the water applied to the filter and that of the effluent, there was found to be less alum in the filtered water than in the river water itself.

Inquiry from numerous manufacturers using alum as precipitant in various quantities in excess of the amount used in the experiments, revealed in no instance any incrustation or scaling in the boilers where such filtered water had been used. Communications with the various boiler insurance companies elicited no report of scaling where such water was used. There is no recorded instance where alum-treated water as a drinking water has produced any ill effects upon the consumers.

This work was done by order of the City Council of the City of Providence and under the direction of a commission consisting of the Superintendent of Health, the City Engineer and the Commissioner of Public Works. The immediate supervision of the operation was under the supervision of Dr. C. V. Chapin, the Superintendent of Health and a member of this Association, while the application of the various tests was made under the direction of Mr. Edmund B. Weston, C. E., from whose compilations and reports these abstracts have been taken. Most of the bacteriologic work was done by the writer.

Inasmuch as the writer, as well as every person connected with the experiments, commenced the investigation with the firm belief that successful mechanical filtration was not possible from a bacteriologic view, it must be stated now, after examination

of these figures, that mechanical filtration under these conditions can be firmly indorsed.¹

The foregoing paper and table of percentages was briefly discussed, first by Dr. P. H. Bryce, who thought the facts contained therein were most valuable and that he felt personally that the thanks of the Association were due to Dr. Swarts for submitting them, and by Dr. Rudolf Gering.

THE SURGICAL TREATMENT OF AURAL POLYPI.

BY P. B. WING, M.D.

TACOMA, WASHINGTON.

It is the purpose of this paper to describe in a brief and concise manner the treatment which I have found most effectual for the permanent removal of those morbid growths known and described as aural polypi. Gruber defines aural polypus as a neoplasm originating in the auditory canal or in the deeper parts of the ear, which is pedunculated and consists principally of histologic elements of the soft connective tissue order. Granulations springing from a broader base are generally called polypoid proliferations. These growths have received a great variety of names by different writers, but I am of the opinion that no observer can say that this is a mucous polypus or a fibrous, but that he will find a combination of both mucous and fibroid tissue. I am also of the opinion that all polypi are at the very commencement granulation tissue and that as they grow in size they change in structure, and that they have received their classification from the tissue that happened to be most prominent in each particular case; also that the epithelium covering a polyp has the character of the tissue from which it springs until it is changed by exposure to external influences. A word only as to the cause. I believe that whenever aural polypi and granulations are found, pus is always the cause, and when we come to treatment, we should never lose sight of this fact.

I shall confine myself to the treatment of those that are benign in character and shall make no mention of the tuberculous, syphilitic and malignant.

The first step in treatment is to thoroughly cleanse the ear. There is usually a profuse discharge of fetid pus, and it is for this discharge that patients usually seek relief, for unless the growth is large, the majority of patients are ignorant of its presence. After cleansing the ear as much as possible, the next step is to make out as accurately as we can the origin of the polyp. In small growths, this is usually easy, but in large polypi, that have filled and by long continued pressure caused absorption and dilatation of the canal, this is sometimes difficult and can only be made out approximately by passing a probe around it.

After we are satisfied as to the point of origin, the removal of the growth is the next point for consideration. How shall we best accomplish it? We are all armed with an instrument known as the snare, but I believe it falls far short of filling the purpose for which it was designed. The loop is formed and adjusted to the size of the tumor, and after applying cocain, or in some instances giving chloroform, the loop is passed over the tumor and as near the origin of the growth as possible. The loop is then pulled home. After pulling the loop tightly around the pedicle, Dr. Pomeroy says that he brings the growth

away by two or three jerks. Dr. Sexton says that it is often difficult to cut through the pedicle and they often have to be brought away by avulsion. I feel like making a little stronger statement and say that it is always difficult to cut through the pedicle of a large fibroma, and that I have always had to give the snare a few turns to twist off the growth. I see a reason why a snare can not be made that will work as well on aural as the Jarvis snare does on nasal polypi. After the polypus is removed, or as much of it as is possible with a snare, the hemorrhage, which is seldom severe, can be controlled by hot water or packing with absorbent cotton. I usually wait until the following day before I proceed to treat the stump. In the majority of cases, we are obliged to use some form of cautery, and in my opinion, no form of cautery is equal to chromic acid.

A small bead of the crystals is fused on the end of a silver probe and applied under perfect illumination. After applying the acid, it is well to wait a few seconds watching the effect, and then touch the spot with a little moist cotton on a probe to take up any superfluous acid. I have used chromic acid in this manner for five years in a great number of cases and have found it perfectly safe. It gives almost no pain and its action is easily controlled. A surface treated with chromic acid suppurates little and heals rapidly. After cleansing and treating with chromic acid, I apply a little finely powdered iodoform and boric acid or hydrastis and boric acid and place a pledget of cotton in the ear. The chromic acid can be applied as often as the slough separates, usually every four or five days. The ear is kept clean during the intervals by using a solution of bichlorid of mercury, about 1 to 2,000, and after cleansing and drying, applying either of the above mentioned powders. This treatment is kept up until the pedicle is destroyed and when the growth is removed, the discharge in a large majority of the cases will cease. Small polypi are usually softer and bleed more easily than the large ones. The snare is perhaps more effectual in this class of cases.

However, there are very few cases treated by the snare that do not require subsequent cauterization. In small polypi, where the point of origin can be easily seen, the pedicle may be touched with chromic acid. The acid penetrates the growth, shuts off the blood supply, and in three or four days the polypus dries up, drops off and comes away as a small, black mass. This process is painless and bloodless, has the advantage of being easily done and is very convenient in treatment of children who are afraid of instruments.

Polypoid proliferations more often spring from the wall of the canal and, I think, are dependent upon some previous furuncle. These growths are to be removed by cauterization and I prefer the acids, used with the same precautions as in other places.

There is one condition resembling polypoid proliferation, which should not be confounded with it. I refer to a swollen and protruding mucous membrane of the middle ear, which may project through a perforated drum-head and be mistaken for granulation. Such cases are made worse by the application of any form of cautery. While speaking of cauterization I have not mentioned the galvano-cautery, for while I prefer it in all nose and throat work, I must say that I consider the acid superior in the treatment of the ear. It can be applied on a small wire, which does

¹ The complete report with tables and estimates of construction will be published in the Rhode Island State Board of Health Report for 1894.

not obstruct vision. The electrode is larger, obstructs vision more and is not so easily handled. The acid in most cases is painless and can be applied without the patient knowing it.

I shall mention a few only of the drugs used in such cases. Iodoform and boric acid I have already mentioned as suitable dressings, but they have no influence over the growth of polypi. Tannic acid, alum, etc., are worse than useless. Argentic nitrate may be used to stop a discharge of pus, but I am sure that it stimulates the growth of polypi and of granulations. Hydrogen peroxid is useful only as a cleansing agent and is inferior to a solution of bichlorid of mercury. Notwithstanding all that has been said of alcohol, I believe that it has absolutely no influence over the growth of polypi or granulations, but it does lessen the discharge of pus. Injection of the growth with Monsel's solution is effective, if well done, but is painful and can be used on large polypi only. Patients will ask us if the growth will return and we ask ourselves what shall be done to prevent a recurrence.

Now, I think we are all of the opinion that suppurative disease or caries is always the cause of polypi and of granulations. It is therefore necessary to stop the suppuration and remove all necrotic tissue before we can say that our patient is cured, for polypi and polypoid proliferations will not grow in dry soil like sage brush and cacti in our western deserts, but like toadstools, they require shade and moisture, and this moisture is pus.

Let us always put in practice that old, sound surgical principle that wherever there is pus, let it out if possible and establish free drainage. If the growth returns and if the perforation is small, we should not hesitate to make it larger and when necessary remove one or more of the ossicles, thus establishing free drainage and giving us an opportunity to treat the diseased parts effectually; always remembering, however, that it is not a trifling operation, but must be skilfully performed and subsequently carefully treated, for cases of meningitis following it are not unknown and I think we are too apt to cover our failures and publish our successes.

TUMOR OF THE BRAIN INVOLVING THE OCULAR NERVES.

Specimen presented to the Medical Society of Washington, D. C.

BY CLARENCE R. DUFOUR, PHAR. D., M.D.

WASHINGTON, D. C.

Physician in Charge of Eye Department Eastern Dispensary; Ophthalmologist and Otologist to Sibley Memorial Hospital; Assistant in Eye and Ear Department of Central Dispensary and Emergency Hospital, and Instructor in Ophthalmology and Otolaryngology, Georgetown Medical College.

Mrs. H., widow, age about 56 years was referred to me at the Woman's Clinic, in the summer of 1894, on account of her eyes. Upon examination I found a complete paralysis of the muscles supplied by the third, fourth and sixth nerves, an exophthalmus and optic atrophy, all on left side. I diagnosed the trouble as being in the brain and so told the daughter who accompanied her. I could obtain no specific history. She had been operated upon some months previous for empyema of left antrum, the opening being made in the cavity of second molar tooth; there was free drainage through the nostril when I saw her. I kept the antrum well washed out with sol. boric acid and gave her sat. sol. iodid of potassium, 10 gtt. three times daily, increasing one drop

daily, until she was taking 30 gtt. three times daily. Any attempt to increase this amount produced such constitutional disturbance that it could not be done. She was kept on this treatment until complete symptoms of iodism were manifested, when it was changed to 1-16 gr. bichlorid of mercury and 3 grs. potassium iodid three times daily, and continued for months with occasional intermission of a few days. No result whatever from the treatment. About the middle of the summer she began to complain of intense pain in her head, which at first yielded to anodyne treatment but which soon became constant and nothing but morphia would allay. About this time there began to be symptoms of loss of sensation on side of face and anesthesia of cornea, indicating that the first division of the fifth nerve was being implicated. This condition continued, with no abatement of the symptoms; she had periods of hallucinations, and as her daughter was obliged to work away from home, and there being no one to leave the mother with, the latter was sent to the hospital. It was thought best to reopen the antrum so as to establish freer drainage; this was done, considerable pus escaping. It was then washed out with antiseptic solution two to three times daily. An examination of the urine was made with results as follows: Amber in color, cloudy ppt., acid reaction; small amount of albumin, epithelial cells and pus were found. After operation on antrum the pain in head subsided for a few days but began again and continued with occasional periods of intermission. She was discharged from hospital in the early part of November. Her condition gradually became worse, her right eye began to show symptoms of incipient atrophy of the optic nerve and an external squint was manifested. She was able to go about until April 1895 when she had to go to bed. She grew worse, her mind wandered and word deafness became manifest. On May 3 she died. On the following morning the skull was opened and the brain removed; It was put into a 2 per cent. solution of formalin, and a few days later the examination revealed the following condition: Gumma of dura mater in the anterior part of left middle fossa; this involved by extension the left anterior temporo-sphenoidal lobe; the growth surrounded the internal carotid artery, exerting pressure on the cavernous sinus and involved the left optic nerve at the commissural origin; considerable edema of the left anterior sphenoidal lobe. A second and smaller gumma involved that part of the brain mass which constitutes the left olfactory convolution; the third and smallest lay in the angle at the right optic commissure. The bone around the first growth had lost its compact covering and had become porous; the dura was very adherent to the bone. The ocular conditions during life were cleared up, I think, satisfactorily by the findings at the post-mortem. The cavernous sinus receives anteriorly the ophthalmic vein through the sphenoidal fissure, and on its inner walls is found the internal carotid artery and the sixth nerve; on its outer wall are the third, fourth and the first division of the fifth nerve.

The pressure exerted by the tumor upon the sinus explains the paralysis of the muscles and the anesthesia of cornea, etc., this pressure together with pressure upon the ophthalmic vein, accounts for the exophthalmus by preventing the return flow of blood through the angular and ophthalmic veins into the cavernous sinus. The pressure also being exerted

upon the optic nerve in front of the chiasm, was the cause of the optic atrophy of left eye. The edema of the temporo-sphenoidal lobe, would, I think, satisfactorily explain the word deafness. The atrophy of the right eye was due to the smallest tumor in the angle of the right optic commissure. The cause of the external strabismus is somewhat obscure, as there was no implication of the third nerve on that side; my opinion is that there was pressure exerted upon this nerve in the region of the sphenoidal fissure, probably as it passed through it. The case was referred to me by Dr. Heiberger, and the post-mortem was made by Dr. D. S. Lamb of the Army Medical Museum, of this city.

OBSERVATIONS ON CONGENITAL DISLOCATION OF THE HIP.

BY BERNARD E. BRODHURST, F.R.C.S.

SENIOR SURGEON TO THE ROYAL ORTHOPEDIC HOSPITAL, ETC.
LONDON, ENG.

Congenital dislocations of the hip are for the most part traumatic. Displacements occur also, however, through deficient development.

Any obstruction at birth, whether through malformation of the pelvis or caused by the position of the child—the breech for instance, presenting, or the child or its head being unusually large, may occasion this dislocation.

In a breech presentation the thighs are flexed upon the abdomen, so that the head of the femur presses on the posterior and inferior portion of the capsule of the joint. But in this position, the application of the slightest force in downward traction will displace the head of the bone and cause it to pass away from the acetabulum and to lie upon its brim. And lying on the border of the cotyloid cavity, extension of the limb at birth is alone sufficient to displace the head beyond the brim. The blunt hook or the finger in the bend of the thigh, to facilitate and hasten the birth, may easily thus displace the head of the bone. And, indeed, such is the result of downward traction. A sensation of sudden yielding of the limb is felt by the hand of the accoucheur, as the head of the bone is displaced from its socket, and at the same time a click is heard. At that moment the caput femoris escapes from the acetabulum, and is found lying immediately beyond the brim of the cotyloid cavity. It is only after the weight of the child has been borne on the feet, as in standing and in walking, that the head of the femur arrives at the external iliac fossa. Shortening of the limb necessarily increases as the head of the femur becomes farther removed from the acetabulum and lies upon the dorsum of the ilium, and, equally, lameness increases.

Dr. Tyler Smith informed me that such was his experience in regard to these accidents at birth.

After my essay¹ on this subject was published, I saw two cases of congenital dislocation with Dr. Tyler Smith. One was a boy, aged fifteen months, with dislocation of the left femur, and the other was a girl, aged five months, also with dislocation of the left femur. The boy was a well-developed and large child and the girl had a large head. There was not any other abnormality in either of these children. In both birth was considerably delayed; in the first by

a breech presentation, and in the second by the large head. In each case reduction of the dislocation was easily effected, and there was not any subsequent displacement.

Some imagine that these dislocations are not truly congenital because they are not observed at birth, nor until efforts are made to walk. Then, if the child falls as probably he will, it is supposed that in falling he has dislocated his hip. But dislocation does not occur in this manner. And without intending to mislead, parents are apt to connect the lameness with the fall, forgetting that the child has always been more or less lame and unable to walk.

It has already been stated that children in whom this dislocation occurs are not infrequently unusually large. This was especially remarked with regard to two boys in St. George's Hospital. I admitted these boys as in-patients, each having congenital dislocation of both hips. One aged twelve years, was as big as a large boy of fourteen, and the other, aged fourteen was like a strong boy of sixteen or seventeen. So much was this the case that doubt was expressed on this question of age, and special inquiry was made, when the facts were verified. And in the case referred to by Mr. Holmes,² and recorded at greater length by myself,³ in which the right femur was dislocated, the child's head was of unusual size. Also in a case where I operated with Dr. De la Cour, and where both hips were dislocated the head was enormous.

But traumatic congenital dislocation does not alone occur at birth; it may also be occasioned *in utero*. I have recorded several instances where, as the result of accident and shock, spasmodic action was set up, and this was followed by dislocation and fracture and distortion.

Cruveilhier⁴ has given a representation of a full-grown fetus with luxation of the heads of the thigh-bones, and with clubbed hands and feet; and he observed that the heads of the thigh-bones, as well as the cotyloid cavities, were progressing to their normal development. Also, there is found in the hydrocephalic and the anencephalic fetus every form of luxation and subluxation, together with muscular retraction in every variety.

Grawitz⁵ records that in every case examined by him there was not only dislocation of the hip, but also club foot, club hands, scoliosis, ectopium abdominis, spina bifida, and other deformities and malformations present. And such is also the case with Mr. Lockwood's⁷ specimens; they are malformations and deformities due to arrest of development.

In pathologic museums dislocations, occurring whether *in utero* or at birth, whether alone or complicated with fracture or distortion, with malformation or monstrosity, whether development is complete or arrested or irregular, are all treated as though they depended on a common cause; and thus much confusion has arisen and misunderstanding.

Many of these deformities are wrongly styled dislocations. Neither was the head of the femur planned to occupy an acetabulum, nor is there an acetabulum to occupy; they are malformations. And

some of the examples in pathologic museums which are labeled "congenital dislocation," have nothing in common with this class of affection, but are results of disease, whether in the adult or in the child.

Thus I have endeavored to show that the agencies producing congenital dislocation are various, and that the conditions of the femoral head and of the acetabulum vary as the period at which dislocation is produced varies. And, since there are varieties of congenital displacements of the hip, treatment must also vary. For instance, when the child is well developed, and there is no other abnormality existing, reduction of the dislocation may be effected within two years after birth; and this period may be extended to three or four years when exercise has not been permitted. The *caput femoris* may then not only be easily reduced, but it will probably be retained in the acetabulum. But after this time the acetabulum becomes more or less filled up with fatty, or with fatty and fibrous matter, and retraction of the trochanteric muscles takes place; so that, even though the head of the femur may be drawn down, difficulty will probably be experienced in retaining it *in situ*.

The head of the femur in such cases is usually of the normal size, and it is covered with cartilage. It remains unaltered or scarcely altered in shape until ten or twelve years of age, or even later; in Mr. Canton's case the change was only slight at thirty-two years of age. Also the acetabulum may retain its depth, but it will probably be filled with fatty matter. Such is the case when dislocation has been produced at birth. When, however, dislocation has occurred *in utero* the acetabulum may not become fully developed, as in the case mentioned by Grawitz⁹ where the acetabulum was not more developed than in a fetus of five months.

It is important to determine the length of time during which the acetabulum may be expected to retain its depth and cartilage and the head of the femur its size. And in illustration of this question I will refer to specimens taken from a boy 16 years of age by Fournier, and presented by him at the Société Anatomique, of which Professor Cruveilhier was president, and on this occasion in the Chair.

"The cotyloid cavity," says Fournier, "retains its form, except that the outer lip is slightly flattened; also it retains its depth and cartilage. The cavity contains a fatty substance, with which it is entirely filled." A new cavity for the head of the femur had been formed, and the head itself was somewhat flattened, but it retained its normal size, and it was covered with cartilage. There was no trace of the round ligament. Inasmuch as there was a history of a fall and subsequent lameness when the child was three years of age, M. Broca raised the question whether this was a congenital or a traumatic dislocation; and M. Legendre observed that congenital dislocation usually passed unobserved until the child began to stand or walk, and if he then fell it was supposed that dislocation occurred at that time. Whereupon Cruveilhier summed up the discussion, and expressed his opinion that neither the position of the femoral head, nor the condition of the cotyloid cavity, nor the absence of the round ligament, were characters sufficiently decisive to enable him to determine whether this was a congenital dislocation or an old traumatic dislocation—"de décider si la lux-

ation est congénitale ou seulement traumatique et ancienne."

Thus Cruveilhier, than whom no one was better able to judge, acknowledged that in congenital dislocation of the hip, even after sixteen years, the acetabulum may retain its form, depth, and cartilage, and the femoral head its size and cartilage.

I have many times found that the depth of the acetabulum was normal at various ages and up to twelve years; and having first ascertained with a needle probe that such was the case, I have proceeded to replace the head of the femur. But if there was difficulty in overcoming the force of the retracted muscles, I have divided these subcutaneously, viz., the trochanteric muscles and the adductor longus. Lying as it does, superficially, it is easy to judge of the size and shape of the *caput femoris*, and to know with certainty if it can occupy such a cavity as the acetabulum.

Having thus divided the various muscles at their several insertions, the head of the femur may be drawn down and firmly fixed with bandages, and with weights attached to the knee and the ankle. The head of the bone remains fixed, and there is no tendency to displacement, so that after four weeks passive movements may be instituted. In another fortnight active movements in the recumbent position are allowed to commence; and when the limb can be fairly abducted and flexed voluntarily, the patient is fitted with a suitable support, and is then allowed to stand and walk.

Fifty-two cases of this form of dislocation have come under my care during the last thirty years; and perhaps the following case will sufficiently illustrate the manner in which I have treated a large number of similar dislocations.

In April, 1895, I divided, with Mr. Henry Baker and Mr. Bailey, the trochanteric muscles and the adductor longus in the left femur of a well-developed and healthy girl 12 years of age, in whom there was not any other abnormality present, having previously probed the acetabulum to ascertain its depth. The femoral head was then dislodged and drawn down. Extension was made on the fourth day, when the wounds had healed; and the head of the femur was then firmly fixed in the acetabulum; from which there was no tendency to escape. The hip-joint was firmly bandaged and extension was kept up day and night. In the course of four weeks passive movements were instituted, and two weeks later active movements were made in the recumbent position. In twelve weeks she was fitted with a hip support, and was allowed to stand and walk. In standing both limbs were of the same length; and although there was slight yielding of the limb, there was no displacement in walking. In July the child walked firmly and without limping; and when recumbent she could flex the thigh entirely on the abdomen.

Where the acetabulum is so much filled up that it is impossible for the *caput femoris* to find a lodgment, I have with a specially curved gouge removed so much of the deposit as I could subcutaneously, to deepen the cavity sufficiently to retain the head of the femur; but I have not done this through an open wound, after the manner of Professor Lorenz, of Vienna, and of Dr. Hoffa, of Würzburg; nor have I found any difficulty in working the gouge subcutane-

⁹ Op. cit.

⁹ *Bulletins de la Société Anatomique*, 1855, p. 267.

ously. But where the gouge has to be used the joint movements are less free, and there is a tendency to ankylosis.

Notwithstanding, this operation is a great gain when the dislocation is single or, after good motion has been established on one side, when dislocation is double. When consolidation has taken place, and a new articulation has been formed, as in Fournier's case I never interfere; but at any period before consolidation is complete, the head of the femur may be drawn down after the trochanteric muscles have been divided, and with or without the gouge, the head of the femur may be safely and permanently restored to the acetabulum.

AN ANTISEPTIC TABLET FOR NASAL WASH.

BY JOHN EDWIN RHODES, M.D.

CHICAGO.

The necessity of a cleansing and an antiseptic wash for the nasal cavities is indicated in a variety of conditions. In cases of simple chronic catarrhal inflammation in which there is an excess of mucus which gathers and forms crusts in the cavities, often due to a slight nasal obstruction and accompanied with an unpleasant "catarrhal odor," the indications for treatment are often chiefly fulfilled by some antiseptic wash which will effectually dislodge the secretions and counteract the odor. In another class of cases instead of obstruction, we find an enlarged passage, atrophy of the membrane, and sometimes of the turbinated bones. Here even an exaggerated expiratory blast of air is inefficient in dislodging the secretion. This rapidly dries upon the surface of fine membrane, decomposes and causes pathologic changes in the tissues, and the patient gives as one of the most distressing features of the condition the bad odor that accompanies it. Here there is an indication for an agent that will both cleanse the nasal passages, disinfect them and stimulate the mucous glands. After operations of various kinds, as the removal of exostoses, the cauterization of the membrane, the removal of polypi, tumors, etc., an agent is needed that will render the parts thoroughly aseptic until healing has taken place. In operations about the fauces, the naso-pharynx, the pharynx, the tonsils, it is always advisable to use some strongly antiseptic solution as a spray or gargle for a few days succeeding the operation.

To meet such indications as have been briefly enumerated above the following formula has been found to possess the requisite agents in suitable proportions. The tablets can be employed in all conditions, and are unirritating if used in the strength of one tablet in from one-half to two-thirds of a glass of lukewarm water. In cleansing the nares it is much to be preferred that the patient should draw the water gently through the passages from the hand than to use any kind of a douche, as the latter in very many cases is improperly used, and the liquid is carried through the nasal passages with such force as to do local damage and perhaps reach the middle ear through the Eustachian tubes and set up a middle ear inflammation. This formula has been thoroughly tested by use in a large number of cases in private practice in the last two years, and is more satisfactory than any agents I have ever used for like purposes.

It has been put up in the form of compressed tab-

lets, which, as prepared by Gale & Blocki, are readily soluble, and in every way satisfactory. Each tablet contains the amount indicated in the formula.

MYRINGITIS ACUTA—MYRINGITIS BULLOSA.

BY FRANK ALLPORT, M.D.

PROFESSOR OF CLINICAL OPHTHALMOLOGY AND OTOLGY IN THE MINNESOTA STATE UNIVERSITY, PRESIDENT OF THE MINNESOTA STATE MEDICAL SOCIETY, ETC.

MINNEAPOLIS, MINN.

Miss M. C., age 20; left ear; general health not good; has had naso-pharyngeal colds for two or three weeks, accompanied by a hard cough. Nov. 11, 1895, at about 11 P.M., experienced suddenly a severe earache, which continued with increasing severity till the morning of November 12, when I was consulted. I found the view of the membrana tympanum obstructed by three large bullæ situated as follows: One at the upper anterior quadrant, extending down nearly to the inferior extremity of the handle of the malleus. This was large and deeply congested, the redness passing on to the meatal wall, as it joins the drum-head.

Another was situated at the junction of the drum-head with the posterior meatal wall, and was more on the latter than the former. This was also much inflamed and large. Another blister occurred exactly at the inferior extremity of the malleus, and was smaller than the others—quite white and not inflamed. A cluster of prominent blood-vessels extended from this to the posterior blister. The bullæ were separate and distinct, for I punctured all three, as each one required a separate incision to liberate its individual serous fluid. I was careful not to penetrate beneath the dermic layer of the membrane, and a thorough inflation of the middle ear with the catheter and air bag after the puncture was made evidenced an intact condition of the underlying membranous coats. The hearing in this ear was somewhat but not markedly reduced. The case was seen by Dr. W. N. Porteus, of this city, at my request.

November 13, I found the blisters all thoroughly collapsed; some membranous inflammation, no pain, slept well, hearing almost completely restored. November 19, drum-head fully restored to a normal appearance and hearing perfect.

THE DEGENERATE EAR.

Read in the Section on Neurology and Medical Jurisprudence, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY EUGENE S. TALBOT, M.D.

FELLOW OF THE CHICAGO ACADEMY OF MEDICINE.
CHICAGO.

(Concluded from page 58.)

Figures 10, 11 and 12 illustrate the different stages of excessive and arrested development of the helix. For the purpose of giving a better description of the stigmata of the ear I have divided the ear into upper, middle and lower third. Figure 10 shows arrest of the helix as far up as the upper third, while the upper part is well developed. Figure 11 shows the helix normally developed. Figure 12 illustrates the lower

third normally developed, while the upper middle and upper third are excessively developed.

When the whole or a large part of the helix is arrested the ear is usually (not always), larger and the antihelix is excessively developed. On the other hand, when the whole helix or larger part is excessively developed the ear is usually (not always) small and thick, with arrested antihelix. When the ear is at or near an angle of 90 degrees the helix is usually quite or entirely arrested or very thin. When it is small and at an angle of from 10 to 45 degrees it is usually well developed and thick. The root of the helix is sometimes arrested. When this is the case

Fig. 10.

Fig. 11.

it is lost in the floor of the concha. When normally developed it produces a distinct ridge extending across the floor and when excessively developed it divides the concha into unequal parts. In 465 criminals at Pontiac, there were 236 arrested, 55 medium, 174 excessive; 181 folded, 48 medium, 236 open. Root of helix, normal 157, abnormal 308. In 1,041 criminals at Elmira, there were arrested 771, medium 52, excessive 206; 294 folded, 747 open. Root of helix, 907 normal, 132 abnormal.

The most singular deformity of the helix is the tubercle of Darwin (Fig. 13), which is a little blunt point projecting from the inwardly folded margin or

Fig. 12.

Fig. 13.

helix. When present it is developed at birth and according to Prof. Ludwig Meyer, more frequent in man than in woman. Figure 13 shows ear and tubercle taken from Darwin's "Descent of Man."³ These points not only project in toward the center of the ear, but are often a little outwards from its plane, so as to be visible when the head is viewed from directly in front and behind. They are variable in size and somewhat in position, standing either a little higher or lower; and they sometimes occur on one ear and not on the other. They are not confined to mankind, for Darwin observed a case in one of the spider

monkeys (ateles bulzebuth) in the Zoological Gardens. Dr. E. Ray Lankester tells of another case in a chimpanzee in the garden at Hamburg. The helix obviously consists of the extreme margin of the ear folded inward, and this folding appears to be in some manner connected with the whole external ear being permanently pressed backward. In many monkeys which do not stand high in the order, as baboons and some species of macacus, the upper portion of the ear is slightly pointed and the margin is not at all folded inward; but if the margins were to be thus folded, a slight point would necessarily project inward toward the center and probably a little

Fig. 14.

Fig. 15.

outward from the plane of the ear, and this Darwin believes to be their origin in many cases.

The hundreds of these cases observed by me have always been found among the neurotic and degenerate. As according to Darwin, "when present it is developed at birth," it therefore must have formed when the ear was developing before the fourth month of fetal life. At birth, however, it is not as prominent as it will become when the ear has obtained its full development, although prominent enough to be recognized.

Prof. Meyer finds these tubercles more common among men than women. This is in accordance with the general rule in evolution that women are truer to the type than men. According to Meyer, it is due to

Fig. 16.

Fig. 17.

arrested development of the helix. In my experience, it is due to both excessive and arrest of development of tissues. I have observed not infrequently both conditions upon the helix of one ear. Tubercles may be located upon both ears or upon one. They also vary in number, one only, or sometimes three, even four have been noticed upon one ear.

The position of these tubercles depends entirely upon the shape of the helix. If the helix is turned toward the center of the ear, the tubercles will point in that direction; if at right angles, they will stand at right angles. If the ear lies perfectly flat without a helix, the tubercles will stand in direct line with

³ The Descent of Man, page 15.

the flat ear and point backward or upward; whether they can be observed standing in front, at the side or back, will depend upon the position of the ear to the head. Some ears stand close to the head, others at an angle of ninety degrees. The location of the tubercle upon the helix varies in different individuals. The most frequent localities, however, are at the upper border of the middle third, as illustrated by Darwin; also at any point on the helix from its origin to its insertion; again, just above and below where the root of the antihelix crosses the root of the helix in the floor of the concha. I have also observed upon the left ear of a physician, which measured 3 inches in length, 1.50 in width, and stood almost at right angles, five tubercles in the upper third of the helix, due to arrest of development. Again, one may be located on the outer border looking outward, and the other on the inner border, looking inward. (Fig. 14.)

In one family coming under observation, the grandmother has three tubercles on left ear, one at the lower border of the middle third, one above and below on the root of the helix where the root of the antihelix crosses it in the concha. A daughter has one on the root of each helix, in the concha below the point where the root of the antihelix crosses it.

Fig. 18.

Fig. 19.

The oldest grandchild, eighteen years of age, has the same tubercles in same places as mother, and also half-developed tubercles on the root of the helix above the point where the root of the antihelix crosses the helix. The second grandchild, a boy ten years of age, has a fully developed tubercle upon each root of helix below the point where the root of the antihelix crosses it, and a semi-developed tubercle on each helix just above that point. The third child (Fig. 15), a daughter one year of age, has four tubercles upon the left ear, two on the root of the helix, like grandma, one at lower border of middle third and one at lower border of lower third; on right ear two on root of helix like other side, and a semi-developed tubercle at the lower border of middle third.

It is impossible to illustrate the tubercles on the root of the helix, owing to the fact that they are situated inside the concha. Figures 13, 14 and 15 form an excellent illustration in the regicide, J. Wilkes Booth; one at the top, the other just below the middle of the helix. In Cesare Giovanni Santo, one at the top, the other at the lower third. In Patrick Eugene Joseph Prendergast, one at the locality pointed out by Darwin, the other at the lower third, near the lobule.

A young professional man, 29 years of age, is a marked neurotic; nervous temperament, suffers con-

tinually with indigestion; has insomnia; possesses a good mind, is a great reader; has full forehead, wears glasses for astigmatism; stigmata show arrest of development of the bones of the face and upper jaw; asymmetrical head; V-shaped arch; high vault; arrest of development of the lower jaw; possesses a long, narrow, handle-shaped ear, with arrest of the upper third and outer border of the helix, showing two distinct tubercles, one near the cranium, the other at the outer border as illustrated by Darwin.

A remarkable case is that of a degenerate whose left ear is 2.75 inches in length, 1.12 inches in width, possesses a tubercle at the lower border of the lower third, one at the middle of the upper third upon the border which looks downward toward the concha, and another just on the opposite side of the helix looking upward; the one looking downward is due to arrest of the edges of the helix, the other to excessive development of the outer border of the helix. From what has already been said it will be observed that these tubercles are in all stages of development from a minute point to the size of a large pea.

As stated at the outset, these tubercles are always observed among the neurotics and degenerate classes; they are due to arrest and excessive development of the helix. Sometimes there is a total arrest of the

Fig. 20.

Fig. 21.

helix, giving the ear the appearance of having been cut or burned away. When these tubercles are observed upon one or both ears, marked stigmata are also observed in other parts of the head, face, jaws and body. This is nicely demonstrated in the case of Prendergast.

In the ear illustrated by Darwin, are other points which demonstrate more clearly developmental neurosis, or degeneracy, than his tubercles. Since this ear was modeled by the celebrated sculptor, Woolner, it certainly must be very accurate. The first thing to be noticed is a general arrest of development. This ear is only about two-thirds the normal size and is unusually thick. (I have already observed that when the ear is unusually large, it is also very thin; when unusually small, it is very thick.) The lobule is arrested to such an extent that it is almost obliterated. The tragus and antitragus are almost entirely undeveloped, leaving the concha unprotected. The helix is rolled upon itself, the result of general arrest. The arrest of development of the rim of the helix at two different places and its development in a small sphere, produces the tubercle. From such a degenerate ear, one accustomed to the study of degeneracy could describe the deformities of the face of the individual possessing the ear, without difficulty.

Sometimes these tubercles grow to an immense size; thus, a business man, 35 years of age, possesses

an ear at right angles, with tubercles equal in size on each ear, as large as the end of the little finger; these are located at the upper middle third. The helix is entirely arrested.

Another singular case is that in which the helix of the left ear is excessively developed. At the extreme upper border there is a large tubercle at the inner edge, looking downward; and opposite, on the upper border looking upward, is another of the same size. Both of these are due to excessive development. Another case is that of a baby 14 months old. There are four tubercles on the left ear and none upon the right. One at the upper middle third, one at the ex-

opment of the helix, the antihelix is excessively developed, and *vice versa*.

This would seem to be a natural compensation for the purpose of collecting the waves of sound. In apes the antihelix is rudimentary, thus showing that the helix is most usually developed. It is claimed by some scientists that the antihelix is also wanting in the most pronounced forms of insanity and in criminals. The following are the results of a most thorough investigation of criminals:

At Pontiac, arrested, 195; excessive, 271. At Elmira, arrested, 317; medium, 13; excessive, 722.

Fig. 22.

Fig. 23.

treme top of the helix, both due to arrest of helix; and two on root of helix, in the concha, one anterior, the other posterior to the lower root of the antihelix, making a groove through which it is to pass.

The same exists in a brother and sister, mother and grandmother, and not in the father of the children. They are not, however, exactly alike in all generations, or in the same generation. This is, no doubt, due to malnutrition.

According to Frigerio, the exaggerated tubercle of Darwin is seen exceptionally in normal individuals, rarely in non-hereditary insane; with an average of 36.95 per cent. in hereditary cases and of 27 per cent.

Fig. 24.

Fig. 25.

in neuropathic degenerates, and not so marked in criminals.

I have taken statistics of tubercles of 1,000 so-called normal persons, with the following results: Right 414, left 446. In 100 noted men, right 33, left 29.

In an examination of 1,506 criminals, making 3,012 ears, these were found upon upper third, right 152, left 127; middle third, right 504, left 452; lower third, right 2, left 3; none, 1,772 ears.

ANTHELIX.

Figures 16, 17 and 18 show arrested, medium and excessive development of the antihelix. My experience has been that where there is arrest of devel-

Fig. 26.

Fig. 27.

TRAGUS.

Figures 19, 20 and 21 show arrested, medium and excessive development of the tragus. The tragus and antitragus are most frequently malformed in the degenerate, though the helix and antihelix are more noticeable. One of the peculiar forms of degeneracy noticed in the tragus is a fissure dividing it into two distinct lobes. Sometimes it is very slight, making a long, double tragus with a slight depression in the center. Again, a little deeper, showing two tubercles, and again, two distinct organs.

In an examination of criminals at Pontiac: Arrested, 117; medium, 244; excessive, 124. At Elmira: Arrested, 534; medium, 70; excessive, 427.

Fig. 28.

Fig. 29.

ANTITRAGUS.

Figures 22, 23 and 24 show arrested, medium and excessive development of the antitragus. This organ is very frequently absent among the degenerate classes.

Examination of criminals at Pontiac shows: Arrested, 313; medium, 59; excessive, 76. At Elmira: Arrested, 693; medium, 21; excessive, 216.

LOBULE.

Figures 25, 26 and 27 illustrate long, medium and short lobule. Perhaps no part of the ear has received so much attention by scientists as the lobule. The long, handle-shaped ear (meaning, of course, the

long lobule) is a marked sign of degeneracy; the short ear, without lobule, also denoting arrest of development. Very little, therefore, is left for a normal lobule. So frequent do we find these conditions among normal individuals that, without other stigmata, either excessive or arrested lobule would be without significance. In extreme cases the lobule

will develop forward and frequently double upon itself, not unlike the ears in the lower forms of animal life.

Figures 28, 29 and 30 illustrate attached, medium and separated from the face. These conditions have also received considerable weight by scientists and neurologists, as demonstrating stigmata of insanity

Fig. 30.

Fig. 31.

Fig. 32.

Figures 31, 32 and 33 illustrate ears of illegitimate children at birth. Owing to their age their mentality is not fully determinable, but numbers 32 and 33 have every appearance of idiocy.

Figures 34 and 35 show the congenital elephantine ear in monstrosities. For the purposes of comparison, the results of my investigations are given in full.

The tables show that the various parts of the ear are often not in harmony with each other.

In the study of aural relations to degeneracy, it is customary to speak of large, medium, small or handle-shaped ears without setting a definite standard for

comparison. Having ascertained the average size length 2.50 and width 1.25 inches, of a given number of ears of normal persons, it may be stated that an ear which measures below 2 inches can be considered a very short ear, between 2 and 2.25 inches short, between 2.25 and 2.75 inches medium, between 2.75 and 3 inches long, and above 3 inches very long. In regard to width an ear below 1 inch is narrow, between 1 and 1.50 medium, and above 1.50 wide.

Fig. 33.

Fig. 34.

Fig. 35.

There is no means at hand of knowing what changes occur in the length of the ear at different ages over 50 years in normal persons. There seems, however, to be a gradual increase in length and width. I have noticed, casually, the ears of a number of persons on the street, and should judge that a large percentage of people possessed ears from 3 to 3.36 inches in length and from 1.50 upward in width. Comparison of the length and width of the ears of paupers, criminals and the insane, indicates that degenerates possessed much the largest and widest ears.

The statistics show that the ear is not in harmony

in its relation to its various parts, and that so-called normal individuals have just as deformed ears as criminals and the insane.

On comparison of the figures of the table it will be seen that the percentage of deformities of criminals and insane is nearly the same, and taken together is about one-half as great as the normal.

There is a somewhat prevalent theory that persons whose lobule is attached its entire length have insane tendencies. The foregoing data do not corroborate this, since in an examination of 1,000 normal persons 92 per cent. are found to have attached lobules, while among the insane only 47 per cent. was found. It follows that an attached lobule is more common among the normal than among the insane. Among criminals is found 37 per cent., and in noted men 9 per cent. for left ears, 10 per cent. for right ears.

The table shows that the tubercle of Darwin is not always found at the upper part of the middle third of the helix (Fig. 13). Tubercles, practically identical, may be found at any point on its border. These tubercles are obviously similar in appearance and due to the same causes that produce the tubercle of Darwin (arrest and excessive development of the helix). Hence, the theory advanced by Darwin that this tubercle is a rudimentary point on the ear is not sustained. In normal persons 3 per cent. of the tubercles of Darwin occur on the upper third, 37 per cent. middle third, 3 per cent. lower third, in right ears, while in criminals 5 per cent. occur on the upper third, 16 per cent. middle third, 3 per cent. lower third, right ears, and in the insane 8 per cent. upper third, 19 per cent. middle third, and 34 per cent. lower third, right ears. They are obviously more numerous upon the middle third of the helix. There is a larger percentage among normal individuals than with the degenerate class.

The left ear, however, seems to be least affected in either the normal or the degenerate. That these tubercles denote degeneracy may be admitted, but it does not seem probable that it comes under the type of degeneracy to which Darwin ascribes it.

The ear at 90 degrees is said to be a marked sign of degeneracy. The figures, however, do not bear out this claim. In normal persons this occurred in 3 per cent. right and left ears, 4 per cent. and 2 per cent. right and left ears of noted men, 10 per cent. right and left in criminals, and 3 per cent. in the insane.

In the relation of the ears to each other there is found a larger percentage of right ears higher than left ears; in criminals 17 per cent. right were higher than left and only 3 per cent. left higher than right, while in the insane 2 per cent. right were higher than left and 4 per cent. left higher than right. In the 1,000 normal individuals there were more deformities upon the right ear than upon the left. This is also true of the 100 noted men. At the time of the examination of criminals and insane these were not classified, as in the normal persons and noted men, except as to the tubercles of Darwin and the interrelations of the ears.

That the external ear as an organ is tending to disappear is shown by the feeble power of its muscles which, except in cases of reversion or special training, are inactive. Changes in the ear by themselves are merely suggestive and not demonstrative of degeneracy, except in accordance with the general rule that accumulation of defect constitutes strong evidence.

SOCIETY PROCEEDINGS.

Chicago Medico-Legal Society.

Regular Meeting, held in Handel Hall, Jan. 11, 1896.

THE PRESIDENT, DR. E. J. DOERING, in the Chair.

The minutes of the previous meeting were read and approved.

DR. F. E. DANIEL, of Austin, Texas, contributed a paper entitled

A PLEA FOR REFORM IN CRIMINAL JURISPRUDENCE, which was read by the Secretary, DR. JOHN RIDLON, in the absence of the author.

He referred, at the outset, to a paper which he presented on "Castration of Sexual Perverts," read at the International Medico-Legal Congress, held in Chicago in 1893, in which he advocated castration of sexual pervers, and especially as applied to rapists, as being more humane, more rational, and more effective as a deterrent than hanging, and more in accord with science, progress and an enlightened civilization; not as a penalty, but as a therapeutic measure in some cases, and prophylactic in all, for the present protection of society, and as a guarantee against a like progeny to curse future generations. Incidentally the author advocated the castration of certain criminals also in this paper, and for the same reasons. In the light of the rapid and alarming increase of crime and criminals in this country, it is evident not only that there is something radically wrong with our system in dealing with crime and criminals: that our penal methods are a dismal failure, but that reform has become an imperative, pressing and immediate necessity. According to the United States census for 1890, there were in 1850, 6,737 prisoners in the United States, or one to every 3,442 of population. In 1890 there were 82,329 prisoners, or one to every 757 of population. The end and object of all penal enactments are supposed to be the protection of society against crime and criminals, and it is unfortunate that no measures are provided as a protection against this increase, principally by heredity. Nothing could testify more emphatically to the inadequacy of our system than the figures just given, nor appeal more forcibly for reform. The thinking members of the medical profession are being rapidly converted to the belief that crime is a disease: that criminals are sick persons, and that their condition calls for a more enlightened method of management. They know that many, if not most of them, are subjects of hereditary transmissions of vicious temperament, and all of them the victims of vicious environment.

The classification of criminals can only be done by medical men. When the character of the crime has been determined by the court, it would seem to be in accord with the requirements of the case and the dictates of an enlightened humanity, that there should be a commission of medical men to diagnose the criminal and prescribe the course which is best calculated to meet the demands. If it be one of the curable class, the treatment, consisting of restraint, discipline, hygiene, education, environment and healthy labor should be such as to induce a determination never to offend again. Pride and self-respect should be fostered, for they are the highest incentives in life to good behavior. The term of imprisonment should depend upon the progress made in reformation, and on good behavior: the culprit made to realize that when he gives evidence of fitness to be trusted with his liberty it will be restored to him. The incurable—the born criminal of Lombroso—should be dealt with as a permanent enemy to society, and the first aim in his case, after sequestration, should be precautions against a progeny. When a man has been diagnosed as a natural criminal, twice convicted of any felony, along with the forfeiture of liberty for life and all other rights, he certainly should be deprived of the right to inflict upon the next generation a progeny sure to be like him. Why not? Can any one give a single reason why this right should be respected when all others are taken away? The author thinks not. The criminal insane should also be embraced in this category. Were it understood that being insane at the time of the crime, or becoming so after, makes no difference, and that castration is to follow, sane or insane, there would be fewer pleas of insanity, and thus would be stopped one loophole of escape by which

many defeat the ends of justice. The author then quoted the case of the notorious Jukes family, with which the readers of the JOURNAL are familiar.

Capital punishment is becoming more and more abhorrent to thinking people, and is being very generally condemned by medical writers as barbarous, useless and unjustifiable. Castration is rapidly growing in popular favor as a substitute for it. In my State (Texas) the agitation of the subject has become a movement. At the last session of the Legislature a bill to that end was actually introduced and found favor. But owing to other and exciting questions, it was pigeon-holed and lost sight of. Texas may yet set the example in this rational reform. Even a decade ago there was much intolerance on the subject, and one was bold indeed who would advocate it. Dugdale in his history of the Jukes was clearly of the opinion that castration was the only rational thing for the born criminal, but he was afraid to say so. Flint quotes him as saying: "In dealing with habitual typical criminals, where we can not accomplish individual cures, we must organize extinction of their race. They must be sternly cut off from perpetuating a noisome progeny either by propagation, or perversion of a coming generation. The old laws attempted this extinction by hanging." And, in commenting upon this sentence, Flint says: "Dugdale evidently did not care to suggest a method of organizing extinction of their race;" but one less severe than hanging readily suggests itself. It would not be difficult to devise a method of sterilization of irreclaimable born criminals which would not offend sentimental public opinion: this to be applied, not as a punishment for any particular class of crime, but merely for protection of society, and after a full scientific investigation of every case.

Dr. Daniel closed his contribution in the following words: "The time has come, and the occasion demands that science should boldly advance its standard and plant it upon the bulwarks of entrenched ignorance, bigotry and intolerance and compel attention. Humanity demands it: public safety demands it. By an organized effort on the part of the two learned professions, Congress can no doubt be aroused to the necessity of being advised by them and induced to create a department of public health and hygiene. Its ramifications extending into each State, the knowledge necessary to intelligent legislation in the interest of society and the public welfare will then find its way to utilization through legislatures, however unwilling, and reform will be the order of the day."

MR. R. W. McCLAUGHRY, Superintendent of the Illinois State Reformatory at Pontiac, discussed

THE HABITUAL CRIMINAL.

He first defined the word habit which, according to the Standard Dictionary, "is an acquired disposition to reproduce certain acts already performed several times, and which, by this repetition, become more easy, more rapid, and more sure. It is an acquired instinct, a second nature." Crime is well defined as an act of which the State disapproves and for which it provides a penalty. Crime has been ascribed by many writers to a lack of will, and while this expression is too indefinite to form a satisfactory explanation of many species of crime, it can be directly applied to the habitual criminal. First among the characteristics of the habitual criminal, even before his inordinate vanity, and his faculty for colossal, gratuitous, aimless lying, stand his lack of will power and his absolute disregard of consequences. The author then drew a distinction between the habitual and the professional criminal. The expression "habitual criminal" was a synthetic term and included many varieties of the malefactor. The moral idiot, the born criminal, the professional criminal and the frequent criminal, were all correctly described as habitual. While they formed connecting links in the criminal chain, they were still separate, and to the expert observer there could be no confusion. The professional criminal he defined as "one who daily or frequently repeats, with a fair certainty of escaping detection, the same crime or misdemeanor which furnishes him with a regular and assured livelihood." There were not many varieties of criminals who could properly be placed in this class. Perhaps a fair instance of the type was the receiver of stolen goods, the professional "fence." Never, or rarely, committing a direct offense against either person or property, this type of criminal thrives upon the proceeds of crime, does more by precept, suggestion and "pressure" of various kinds to educate and turn out upon society finished and dangerous criminals, than any other agency that the devil has in his employ for this purpose. He is the modern type of Dickens' Fagin. This Fagin is the meanest, most treacherous, conscienceless, cowardly scoundrel in the whole catalogue of villains. He never permits either agent or operator to retain more than 10 per cent. of the proceeds of the booty that he has risked life or liberty to ob-

tain. To the author's mind, the absolutely typical criminal was the fully developed, habitual thief, and it was in this class that all the signs of mental and physical degeneracy, characteristic of the crime class, were found. It was in this class that we find with startling certainty and frequency the malformations of the skull and the various anomalies which indicate a badly balanced organization. All these malformations could be found in persons of undoubted honesty and good reputation, but it had been proved by a series of searching and thorough experiments, that these anomalies are more than five times as numerous among criminals as they are among non-criminals. Moreover, it is rare to find a normal man presenting more than one of these anomalies, while it is almost impossible to find an habitual thief in whose physique there are not several typical malformations.

The question of responsibility and punishment of criminals is one on which the most widely divergent opinions are held by various schools of scientists and philosophers. According to the Italian school the criminal is an atavistic anomaly. He can not help it. It is not his fault that he was born with a natural inclination to do evil. His crime is the result of a malformation of his brain, and in the opinion of Mr. McClaughry it is fair to punish a man for his deformity. To illustrate this point, he selected the case of Prendergast, the assassin of Mayor Harrison. It was claimed by the lawyers and experts for the defense that the assassin was insane. "The fact that Prendergast, an uneducated person, seriously considered himself qualified to discharge the duties of Corporation Counsel would, he thought, indicate of itself that his mind was unbalanced. Moreover, the comparative measurements of Prendergast's skull proved that he possessed all the stigmata of the paranoiac. But he did not consider that the fact of Prendergast being unbalanced rendered his execution unjust either to society or to himself. As regards society he was one of its vermin, and as such his removal was necessary. This removal could have been equally accomplished by confinement for life, but so strong is the power of suggestion upon people of his kind that, if it had been for the unfaltering and decisive action of public opinion in his case, we would have seen an epidemic of assassination in various parts of the country. The verdict in Prendergast's trial was a foregone conclusion, the same as was the verdict in the case of Guiteau, and of the Chicago anarchists. The three verdicts were the result of those periodical outbursts of public sentiment, against which the eloquence of council, legal technicalities, or even evidence itself are of no avail. Their results may be harsh, but they are healthy. They cleanse, for a time at least, the moral atmosphere."

Concerning the criminal who had passed beyond the reach of preliminary or preventive measures, the author said that the joint experience of hundreds of persons, who had for years made daily observation of this class, was to the effect that the habitual criminal was absolutely incurable. More than this, he was a constant source of untold harm to society, and should be eradicated, as we eradicate the germs of a pestilence. In the first place it should be carefully established by the courts acting under certain well understood principles, whether or not the accused is a habitual criminal. The failure to put this or that technical phrase in the indictment should be no bar to the submission to the court of conclusive evidence showing his real criminal character. Under our present system the face of the accused may be as familiar to the judge as is that of the State's Attorney. He may have been convicted before the same judge twenty times; but if, on the twenty-first trial, the fact has not been set forth in the indictment, no evidence can be permitted to prove it. Now, upon its being clearly proved that the accused is a perpetual criminal, a social parasite, who has given repeated evidence that his liberty is a direct and serious menace to the community the punishment should be decisive. The penalty should be no longer correctional but preventive, and imprisonment for life appears to offer the only solution of the problem. This, the essayist admits, is drastic treatment, but it is required. The greatest latitude should be allowed the courts and the prison authorities in the matter of imprisonment. Take our courts and our prison management out of politics and we will have removed the greatest obstacle to the protection of society, through the administration of its laws. Justice should no longer be represented as blind-folded. Take the bandage from her eyes and then she will see to weigh other things beside the mere criminal act in her balance. She will weigh, not only the circumstances surrounding the act itself, but the past and the probabilities of the future in the case of each offender, and when she is permitted to do this she will see that only permanent removal from society will meet its needs so far as regards that contagious pest, the incurable habitual criminal.

DR. HAMILTON D. WEY, Superintendent of the New York State Reformatory at Elmira, followed with a paper entitled

MORBID SEXUALITY IN A REFORMATORY.

in which he said that the medical man swayed by no sentimentality should in a scientific spirit accept conditions as he finds them, not confounding nor mistaking a *post hoc* for a *propter hoc*. The spirit and function of the law constitute the protection of society and conservation of morality, the according of privileges and restraint of license, while the formulation of the several statutes looking to the above end is based upon a knowledge of mankind as at present existing, and not upon an ideal man. The author is of the opinion that perverse, morbid and pathologic sexuality exists to a greater degree than is commonly supposed by those who had given the subject little consideration and attention. Abnormal sexuality was found in the city, and it flourished in the country. Nor was the speaker convinced that the morals of the country in this respect were superior to those of the city. It is not surprising that sexual malpractices are found in penal institutions despite the exercise of most constant and unrelaxing supervision. As the medical officer of a State Reformatory, receiving males between 16 and 30 years of age, upon first conviction of felony, it had fallen to him to have at various times under his observation and care a greater or less number whose sexuality found expression in unnatural ways during imprisonment. All the boys and men in the institution with which he is connected were sexual free-livers prior to conviction. Some habitually gratified themselves in a natural manner and were sexually normal, but under the restraining influences of imprisonment became either active or passive pederasts according to opportunity, or practiced onanism. The most common and widespread phase of sexual activity that comes to his notice is masturbation. He does not think that there is the unanimity of opinion there should be between alienists and prison physicians as to the ultimate disastrous effects upon the nervous system and mind, and coincidentally upon the body, of long-continued, frequently indulged-in masturbation. Each views the habit from a different standpoint and under different conditions, and each is correct in his conclusions from his point of observation. The former comes to look upon the sexual deviation he sees in mental disease as an outcome and accompaniment of insanity and refers to cases in which exaggerated and morbid sexuality, obscene language, indecent exposure, etc., appeared after mental disease had declared itself. These conditions are the concomitants of insanity—the effects. The trained eye of the prison physician speedily recognizes the habitual masturbator, detects him in his practices, notes physical and mental decline as self-indulgence increases and intervening periods of sexual quietude decrease in length, until finally there is a lapsing into dementia preceded by a transient and active mania, or melancholia ensues. Indeed, it seems as if some youthful prisoners yield themselves in confinement to morbid sexuality as if this was all that was volitional remaining in them. At this juncture the author dwelt upon several phases of sexual perversion and cited typical cases.

In closing he submitted three propositions:

1. Have prison officials, without the liability of laying themselves open for damages, the right to castrate, asexualize or sterilize a sexually morbid prisoner against his will, when indications of such operation are manifest? And is there the same justification for such surgery as in the operation for the relief of a strangulated hernia and the elevation of depressed bone in a fracture of the skull performed upon the person of a dissenting convict?

2. Is an imprisoned convict competent to execute an instrument declaring his wish to be asexualized and granting immunity from damages for abrogation of sexual capacity? If he be a minor, could he so consent without the concurrence of his parents or guardian: and could the latter compel him, without his consent, to submit to asexualization?

3. On such consent having been voluntarily given and subscribed to in due form in the presence of witnesses, could he at the termination of his imprisonment maintain a suit for damages? If as above stated, could the factor of imprisonment in the case be construed as coercion operating to obtain the consent above named, and become the basis of litigation? The author is not aware that asexualization has been employed in the treatment of those convicted of heinous sexual offenses and the sexually morbid and degenerate criminal. There are, however, precedents for its employment in the treatment of demented whose mental impairment followed perverted sexuality, and in connection with the care of certain defective dependent classes.

MR. MAT. W. PINKERTON, of Chicago, followed with a paper on

THE ECONOMICAL TREATMENT OF THE HABITUAL CRIMINAL.

A comparative study of crime and criminals has led to the

introduction of more humane methods, which have revolutionized the ancient theories of punishment. Theoretically the element of revenge has been eliminated and the security of society, together with the reformation of the offender, made the prime objects. We now aim to do the criminal as little harm and as much good as possible, while protecting the rights and interests of the public at large. The economical treatment of criminals is a question by no means limited to the amount of money involved. There is such a thing as suppressing crime in a manner that increases it in other directions, thus in the aggregate multiplying vice. In the speaker's judgment, our present methods partake largely of this character, and need radical revision. If prevention is better than cure in medicine and the ordinary ills of life, it must be equally true when applied to the evils that infect society. In dealing with criminals he would attack them in their cradles, and not wait until they have propagated a numerous progeny and become fit subjects for the prison or the gallows-tree. He would propose a more vigorous enforcement of existing laws, and the enactment of new ones with especial reference to the children of born or habitual criminals. Such persons should not be permitted to educate their children for the workhouse and penitentiary: to guide the feet of those born with a predilection for crime in the path that terminates at the gibbet. The children of such parents should at the earliest possible age be removed from their care and custody, placed in proper institutions and there reared and educated at the expense of the State, except where the parents are possessed of means, or the ability to earn money, when they should be made to pay for the maintenance of their offspring. To execute such a plan satisfactorily would cost a large sum of money, but it would still be an economical one. The greatest good would be conferred upon the children themselves, who would thus have a fair opportunity to become respectable members of society, instead of thieves, prostitutes and murderers. Such a system would have a decidedly good effect upon the criminal parents themselves. Mr. Pinkerton believes that castration of criminals would increase the morbidity and render the subject more dangerous in all respects, save one. He was hardly willing to admit that this exception would exist, except in the matter of procreation, since depraved fancies and impulses would most assuredly take the place of natural passions. Asexualization would not render desperate criminals docile or reduce their disposition to commit crime. He favors the imprisonment of habitual criminals, without leaving the slightest hope of release while they remain criminals: their children should be provided with proper homes, education and trades, and in adopting new methods, they should be such as will harmonize with humane notions and the progressive spirit of the age.

MR. W. S. ELLIOTT, of the Chicago Bar, discussed

THE LEGAL ASPECT OF THE TREATMENT OF THE HABITUAL AND SEXUAL CRIMINALS.

He stated that his contact with criminals had taught him charity, and he had learned this charity largely through the kindly offices of medical men who had taught him as a criminal lawyer, surveying the terrible crimes which are committed in communities, that nearly all of them are the results of conditions for which the so-called criminal himself was not responsible. Nearly all crime lies behind the criminal himself. He finds from his experience in meeting with people praying for divorces, that their children could never be anything else but animals, for the parents themselves entered into sexual congress merely as animals. Some months ago a mother came to him, asking him to defend her son. She said to him, "My son has the peculiarities which have caused this crime if he is guilty of it, because they are born in him." She also stated that "there was no night during the entire time that she carried that child during the period of gestation that her husband did not have access to her body from four to five times." How could the child be anything else but a sexual pervert, a masturbator. If it were worth while, he could state other cases of a similar character where women apply for divorces under similar conditions, saying that life is a burden to them, and that death is preferable, and that they can see in them the progeny coming from such sexual connections the causes which lead to this perverted condition. We will not be able to devise any method probably which will cure all crime.

The subject of asexualization is submitted for our consideration from at least two different standpoints, each of which would require a different answer, and he would touch briefly upon one point, namely, as to the legality of the supposed beneficial results of castration. So far as its being a proper legal measure as a punishment for crime, it would not be legal: that it would be considered without question an unusually harsh and cruel punishment, which is inhibited by the constitution

of the United States, and, so far as he knows, by the constitution of every State in the Union. It would be illegal, therefore unconstitutional, and he believes it is absolutely impossible to make it constitutionally legal by any legislature of any enlightened State. That they might be able to do it in Texas he deemed it possible, perhaps, but in Illinois or the great States where intelligence is moving forward, men would never consent to such a wicked and outrageous proposition as castration as a punishment for crime. As to the propriety of castration for the purpose of curing people who are given over irretrievably to masturbation and those terrible vices described by Dr. Wey, he thinks it would be just the same as though a leg should be cut off if it were necessary in order to save a man's life. There are a large number of people who are greatly relieved when society lays its hand upon their children, takes them and carries them away into penal reformatories. They are glad to get rid of them and to have society assume their clothing and their board. There are very many parents who would be glad to consent to this act, but over and above all, in the case of a minor it would be necessary for him to have somebody to speak for him. Not to pursue to any further extent the legal aspects of the subject under discussion, Mr. Elliott said he would like to discuss the subject briefly from his own ethical standpoint.

"I think it would be a very unfortunate step to proceed to the punishment of criminals by castration. I do not think that any of us have yet arrived at that degree of perfection where we dare reach out our hand and lay it upon any single fellow being and say, you stand where we may deprive you of that which God invested you with first of all, when he said, 'Increase, multiply and replenish the earth.' If you have that right, you have the right to kill a man, and you have the same right to kill him that you have to castrate him—no greater and no less in one instance than in the other.

"Again, it does not necessarily follow that a criminal is going to procreate a criminal. It does not at all follow that the brightest and most intelligent minds are the product of uncriminal ancestry; for some of the most brilliant minds that have dazzled mankind are nothing more nor less than abnormal forms of illegalized lust, and some of those names which dazzle history,—some of those stars which have shone brightest in the constellations of literature, are bright and brilliant and coruscating simply because of the result of abnormal conditions, and had they not taken that drift they might have taken some criminal form. I have been thrown in close contact with men whose minds were as bright as the morning star, yet who were as vicious as hell at heart and capable of the most damning offenses which, if society knew, it would spurn them. Furthermore, great intellectuality by no means indicates purity of heart, or purity of character. Nor dare you say, nor dare that man say of great personal vigor, power of mind and body and physical courage, that he himself will not be the procreator of criminals and of crime. And there is not a man probably within the sound of my voice, who has been an observer of men and things, who does not know that the men of the finest, strongest bodies and characters become the fathers of dwarfs and insignificant progeny. You can not recall now to your mind scarcely from the great Washington down through all of the proud galaxy of statesmen who have dazzled our political world and our American statesmanship, very many men who have sons that have risen to anything like the commanding position which their fathers have, and many of them have had sons who have disgraced the paternal name, and whose names can be found recognized in the reformatory institutions of this country only by numerals. And it is a well recognized fact, as I understand it, by medical men, that through an atavistic tendency to reproduction in one age men will be of small stature, of criminal tendency possibly, but by happy marriages may in their progeny reproduce splendid, noble specimens of manhood. It seems to me that we are not authorized as human beings to lay our hands upon any citizen and say, 'You have forfeited the rights with which the Almighty God invested you,' but that we will have to go back, in order to benefit our race, to the Sunday school, under the droppings of the sanctuary, and teach those people to grow up into the 'nurture and admonition of the Lord.' I believe castration would make people worse. I do not believe it would make them better."

At the close of Mr. Elliott's remarks, Dr. D. R. Brower moved that a committee of three be appointed by the President to draft resolutions embodying and expressing the leading principles of the papers that had been read, and that the report be submitted at a subsequent meeting of the Society. Carried.

The President appointed on this committee Drs. D. R. Brower, James Barry and G. Frank Lydston.

On motion, the Society adjourned.

SELECTIONS.

The Klebs-Loeffler Bacillus and Its Mystifying Congeners.—A discussion has recently taken place at the Pathological Society of London that has caused considerable confusion in the minds of those who have been hoping for a greater clearness of views regarding the causative factors of diphtheria. The editor of the *Medical Press and Circular* expresses this growing confusion in a leading article entitled "Bacteriologists to the Rescue," the gist of which is the need for a clearer differentiation of the bacilli that occur in the different conditions, sometimes pathologic and sometimes not pathologic, of the mouth, throat and nares. The articles is as follows:

The more the subject of the bacillus diphtheriae and its congeners is discussed the more confused does it appear, witness the recent discussion at the Pathological Society of London. We have got used to hearing bacteriologists speak glibly of the long and the short variety, but we had scarcely become familiar with this summary classification before we were confronted with a subdivision into "big ends and little ends," that is, in technical parlance the clubbed and non-clubbed. As if this were not enough to puzzle us we are now asked to consider an apparently unlimited number of pseudo-diphtheria bacilli some of which are morphologically indistinguishable from the general article. The difficulty, not to say the impossibility, of distinguishing between the genuine and the spurious bacillus is such that reliance can, it seems, only be placed on experiments on animals with the object of determining the virulence of the incriminated organism. A bacillus, however successfully it impersonates the pathogenic microbe, is contemptuously dismissed if, on inoculation into animals, it does not forthwith bring the life of the animal aforesaid to a premature and more or less violent conclusion. Unfortunately, although this is the only test we can at present hold on by, the most enthusiastic bacteriologist does not venture to claim that it is absolutely trustworthy. Indeed, there is much reason to believe that the virulence or otherwise of a given culture is largely dependent on conditions of environment, such conditions, like so much else in this department of scientific research, being at present very imperfectly understood. Then, again, the pathogenic significance of these numerous varieties, confining our attention for the nonce to the pathogenic organisms, is a matter of controversy. Some observers, possibly the majority, associate the long variety with certain clinical gravity, while the short microbe is credited with determining only mild attacks of the malady. On the other hand, the long bacillus, occasionally, at any rate, fails to correspond to a grave attack, while the short form, it is affirmed, has been known to cause death at short notice. Before we leave the subject we should like to indorse the protest that has been uttered against the misleading term pseudo-diphtheria bacilli—applied to certain non-pathogenic bacilli of the diphtheria type. They are either diphtheria bacilli or they are not, and in the latter case it is not easy to see what assistance can be derived from calling them by a name which is only a negation. We might as well call the colon bacillus the pseudo-typhoid bacillus, to employ the trite analogy suggested by Dr. Kanthack. It is superabundantly evident that several years' work will be required before we shall begin to see clear in this direction. It can be no subject for surprise that there should be many varieties of bacilli conforming to the diphtheria type. There are hosts of vibrios and crowds of bacteria, and analogy would lead one to anticipate that the diphtheria family is not less numerous. What we have to do is to study their morphologic peculiarities and life history, in order to be enabled to distinguish those which are responsible for the production of the syndrome of symptoms which we associate with diphtheria from the others.

Hyperpyrexia in Typhoid Fever.—Dr. Wm. Osler, in the *Bulletin of the Johns Hopkins Hospital*, October, treats of three cases of fever whose temperature exceeded 107°. He says that among the 389 cases of typhoid fever under treatment in the hospital during the first six years of its work, there was only one case (fatal) with a temperature of 107°. Within the past few weeks there have been two cases in which the temperature registered 107° and over. One of these recent cases, A. B., a male was admitted after having been ill about two weeks. For a few days he seemed to be doing very well. "The most unpleasant feature of this case was the constant mental apprehension. On the fourth day after admission the temperature

reached 104°, and then ranged between 103° and 104° till the seventh day. The sponges reduced his temperature fairly well. I saw him at half-past eleven on the seventh day, and he then seemed to be somewhat better than he had been for a few days. He had been delirious through the night and tried to get out of bed. The abdomen was slightly distended. There was no pain in the right iliac fossa. At half-past eleven the temperature was 104°. At 1 P.M., he had a severe shaking chill. The respirations were hurried; there were loud expiratory groans; the expression was that of fright, and the patient cried out that somebody was trying to kill him. The pupils were widely dilated, but equal; the eyes had a wild, vacant stare. He sweated profusely. The temperature at noon was 104.2°; at 1:45 it was 106.2°. About 1:45 the shaking became less. The patient all this time was cyanosed: hands purple, lips blue, face dusky. At 1:45 the pulse could hardly be felt. At this time there was a slight twitching of the left side of the face but no actual convulsion. The cyanosis became more marked, the patient became weaker, the temperature rose at 2 o'clock to 107.5°—the highest recorded temperature we have had in typhoid fever—and he died at 2:45.

"The second case, a colored girl, at present in the hospital, was admitted about the third week of the fever. She looked very ill, and the nervous symptoms were pronounced. She had excessive jactitation, tremor and delirium. The temperature was 103°, and rose at 8 P.M. At 2 A.M. it was 102°, and then rose gradually till at 8 A.M. registered 107.2°. With ice-sponging her temperature was reduced very promptly. She was sponged at eight, ten, twelve and two, and by 2 P.M. her temperature was reduced to 102°, and by 8 P.M. to 100°. From that time she did remarkably well."

Experimental Sand Filtration of Water in Pittsburg. There is a general prejudice against household filters, on the ground that they rarely receive the attention which their safe use demands. This prejudice is in some degree well founded, but it should not be extended to city filters, where water is purified by slow and careful sand filtration with all necessary supervision. Sand filters are common in Europe and are likely to be soon adopted by all American cities which now use contaminated river water and are suffering the usual penalty for so doing, viz: excessive typhoid fever mortality.

The Craig Street filter, of the Citizen's League, is an experiment to test the adaptability of the European method to our local conditions. The city water of Pittsburg is being continuously filtered, at the rate of 2,500,000 gallons, per acre, per day, through four feet, six inches of common washed Allegheny river sand, in a manner which may be seen by anyone who cares to visit the plant. (Craig Street, near Fifth Avenue, Bellefield.)

Since October 28, 1895, the sand having at that time settled together thoroughly, the filtered water has been of a uniformly satisfactory character with the exception of a brief interval following the November 12th scraping (when half an inch of sand was removed to prevent continued clogging).

Bacteriologic tests of the filtered and unfiltered water have been made almost every day since September 22, when the filter was started. Two chemic analyses have been made. A few results follow:

		Per cent. of bacteria removed by filter.
September	23	none
"	25	27 per cent.
"	27	46 " "
October	4	69 " "
"	12	89 " "

Soon after this the percentage of bacteria removed by the filter reached and exceeded 99 per cent. It remained approximately the same until the scraping.

I now give for comparison the bacteriologic analyses following the scraping of the filter on November 12. It is generally

supposed that the efficiency of a filter is very much impaired by the cleaning process and that no good work is done until the "Schmutzdecke" is restored. Our experience seems to indicate that good results are obtained in a few hours (93 to 94 per cent. removal) and that the efficiency soon returns to the normal.

		Raw water. Bacteria per Cc.	Filtered water. Bacteria per Cc.
November	12 ¹		13
"	13 ²	505	30
"	14	778	64
"	15	1156	56
"	16	782	8
"	18	946	8
"	19	424	8
"	20	196	6
"	21	612	7
"	23	232	8
"	25	350	4
"	26	176	10
"	29	1414	7
"	30	not counted	

¹ Filter scraped; $\frac{1}{2}$ inch sand removed.

² Twelve hours after second start.

The removal for a few days (November 13 to 16) amounted to 95 per cent. (average). The removal for the next nine days averaged 98.66 per cent.

CHEMIC ANALYSIS.

	Raw. Part. per 100,000.	Filtered. Parts per 100,000	Percentage re- moved by filtration.
October 31, 1895.			
Free ammonia00093	.00026	72 per cent.
Albuminoid ammonia00620	.00180	71 per cent.

Aside from the chemic and bacteriologic improvements which filtration effects, it is also interesting to note that the filtered water is superior to the raw in the following respects:

Odor, taste, suspended matter and most of the dissolved coloring matters are removed by the filter. When the filter is at its best, the effluent resembles distilled water and is even more palatable. At present, although the bacteria are being satisfactorily removed, the water has a slight brown color and a very faint opalescence, but is without odor or taste. The raw water just now is very brown, from dissolved vegetable matter, and very muddy also. At the present rate of filtration, the interval between scrapings seems to be about seven weeks.

The experiment thus far has been very encouraging. Our available river sand is suitable for city filtration and it is to be hoped that it will soon be so used. The experiment will be continued for the purpose of testing different rates of filtration, and the intermittent as well as the continuous system.

Additional financial aid for this enterprise will be greatly appreciated. JAMES OTIS HANDY in *Pittsburg Medical Review*.

St. Luke, the Beloved Physician.—The patron saint of medical churchmen is Luke, the writer of the third Gospel. From a book recently issued by Mr. Henry Burton, the following paragraphs have been selected as showing utmost and most recent knowledge of the personality of that immortal name: "Concerning the life of St. Luke the facts are few. While some regard him as being a Grecian by birth, others maintain that he was that nameless one of the two Emmaus travelers. But both these suppositions are set aside by the fact that the Evangelist carefully separates himself from those who were "eye-witnesses," which he could not well have done had he taken part in the closing scenes of the Lord's life, or had he been honored with that "infallible proof" of the Lord's resurrection. That he was a Gentile is evident; his speech betrayeth him; for he speaks with a Grecian accent, while Greek idioms are sprinkled over his pages. Tradition, with unanimous voice, represents him as a native of Antioch, in Syria.

Responding to the Divine Voice that bids him "write," St. Luke brings to the task new and special qualifications. Familiar with Old Testament Scriptures at least in their Septuagint form, as his many qualifications show—intimately

acquainted with the Hebrew faith and ritual, he yet brings to his work a mind unwarped by its traditions

And so the Gospel of St. Luke is the Gospel of the world, greeting "all nations, and kindreds, and peoples, and tongues" with its "peace on earth."

The only other fact of the Evangelist's life we will here notice is that of his profession: and we notice this simply because it enters as a factor into his work, reappearing there frequently. He was a physician: and from this fact some have supposed that he was a freedman, since many of the Roman physicians were of that class. But this by no means follows. All physicians were not freedmen: while the language and style of St. Luke show him to be an educated man, one, too, who walked in the upper classes of society. Where he speaks natively, as here in the introduction, he uses a pure Greek, somewhat rounded and ornate, in which there is a total absence of those rusticisms common in St. Mark.

The calling of a physician naturally develops certain powers of analysis and synthesis. It is the art of putting things together. From the seen or felt symptoms he traces out the unseen cause. Setting down the known quantities, by processes of comparison or of elimination he finds the unknown quantity, which is the disease, its nature and its seat. And so on the pages of the third Gospel we frequently find the shadow of the physician.

We recognize the "physician" in St. Luke's habits of observation, his attention to detail, his fondness for grouping together resemblances and contrasts, his fuller reference to miracles of healing, and his psychologic observations. We find in him a student of the humanities. Even in his portrayal of the Christ it is the human side of the Divine nature that he emphasizes; while all through his Gospel, his thought of humanity, like a wide-reaching sky, overlooks and embraces all such earthly distinctions as position, sex or race."

SOCIETY NEWS.

Règlement du XII Congrès International de Médecine, Moscou, 7 (19)—14 (26) Août 1897.

1. Le XII Congrès International de Médecine est placé sous l'Auguste patronage de Son Altesse Impériale le Grand-Duc Serge Alexandrovitch.

2. L'ouverture du Congrès de Moscou aura lieu le 7 (19) Août 1897 et sa clôture le 14 (26) du même mois. Sa durée sera de huit jours.

3. Le Congrès se composera des médecins qui se seront fait inscrire et auxquels il aura été délivré une carte de membre.

Indépendamment des médecins, les personnes munies d'un titre scientifique, qui désirent prendre part aux travaux du Congrès, pourront également en faire partie aux mêmes conditions, mais en qualité de membres extraordinaires. Pourront également en faire partie, en qualité de membres extraordinaires, les vétérinaires, les pharmaciens et les médecins-dentistes.

4. Les personnes qui désirent prendre part au Congrès doivent, pour obtenir leur carte de membre, effectuer un versement de dix roubles (vingt cinq francs). Ce versement leur donne le droit de prendre part à toutes les occupations du Congrès et de recevoir toutes ses publications ainsi qu'un exemplaire des "Travaux du Congrès," aussitôt après leur publication.

Remarque.—Les membres extraordinaires ne prennent part qu'aux travaux des Sections du Congrès dans lesquelles ils se sont fait inscrire. Ils reçoivent toutes ses publications, mais n'ont pas droit de vote dans les questions qui concernent son organisation.

5. En faisant leur versement au Trésorier du Congrès, les membres doivent indiquer exactement et lisiblement leur nom, adresse et profession. Il serait en outre à désirer que ces renseignements fussent accompagnés de la carte de visite du souscripteur.

6. Le but du Congrès est exclusivement scientifique.

7. Les travaux du Congrès se répartissent entre douze Sections: 1° Anatomie (anthropologie, anatomie normale, embryologie et histologie normale); 2° Physiologie (y compris la chimie médicale); 3° Pathologie générale et Anatomie pathologique; 4° Thérapeutique générale (hydrothérapie, climatothérapie, etc.); 5° Pharmacologie, Pharmacognosie et Pharmacie; 6° Maladies internes; 7° Pédiatrie; 8° Maladies nerveuses et mentales; 9° Dermatologie et maladies vénériennes; 10° Chirurgie (y compris les maladies du larynx, de l'oreille et des dents) et Ophthalmologie; 11° Accouchements et gynécologie; 12° Hygiène (y compris la statistique sanitaire, la médecine sociale, l'épidémiologie, l'épizootologie et la science sanitaire technique); 13° Médecine légale.

Remarque.—En cas de nécessité, il pourra encore être organisé des Sous-Sections supplémentaires.

8. La gestion du XII Congrès International de Médecine appartient à la Faculté de Médecine de l'Université Impériale de Moscou. Son organisation générale est confiée à un Comité, présidé par M. le Curateur de l'Arrondissement scolaire de Moscou et composé de tous les membres de la Faculté de Médecine, des présidents des Comités de Sections et de Sous-Sections et de membres honoraires. Les questions concernant l'organisation du Congrès sont confiées aux soins immédiats d'un Comité exécutif présidé par le doyen de la Faculté de Médecine et composé de huit personnes choisies parmi les membres de cette Faculté.

9. Le Comité d'organisation et le Comité exécutif continueront à fonctionner pendant la durée du Congrès.

10. Les séances du Congrès auront lieu chaque jour, soit dans les assemblées générales, soit dans les Sections.

11. Il a été décidé de tenir deux ou trois assemblées générales. L'époque de leur réunion sera déterminée par le Comité d'organisation. A l'ouverture de la première assemblée générale, le président du Comité d'organisation proposera aux membres du Congrès d'élire les présidents honoraires et les secrétaires de ces assemblées.

12. Les heures auxquelles se réuniront les Sections seront fixées par le Comité exécutif après entente avec les présidents des Comités de Sections.

13. Le Comité exécutif, après entente avec les présidents des Comités de Sections, indiquera en temps utile ceux des savants étrangers qui pourront être élus présidents honoraires des Sections.

14. Les assemblées générales ont pour but: a) de décider les questions relatives aux travaux et aux affaires générales du Congrès; b) d'entendre les discours et communications offrant un intérêt général.

15. Ne pourront prononcer des discours dans les assemblées générales que les membres qui auront reçu une invitation à cet effet du Comité d'organisation.

16. Les propositions relatives aux travaux du Congrès devront être communiquées au Comité d'organisation avant le 1er (13) Janvier 1897. Le Comité décidera s'il y a lieu de donner suite à ces propositions ou de les examiner pendant le Congrès.

17. Dans leurs séances les Sections s'occuperont de l'examen des questions et des thèses proposées par leurs présidents et approuvées par le Comité d'organisation. Le principal objet des travaux des Sections consistera dans l'audition des rapports des savants désignés par le Comité et des communications ayant trait à la thèse choisie.

Si le temps le permet, on pourra examiner d'autres communications et d'autres thèses proposées par les membres du Congrès et acceptées par les présidents des Sections qu'elles intéressent.

18. Les questions scientifiques ne pourront être résolues par voie de vote.

19. Le temps assigné à chaque communication ne devra pas dépasser vingt minutes et les orateurs qui prendront part à la discussion ne pourront pas parler plus de cinq minutes chacun.

20. Les membres qui prendront part aux débats devront remettre, le jour même, aux secrétaires des Sections respectives l'exposé écrit de ce qu'ils ont dit pendant la séance.

21. Le français est reconnu comme la langue officielle du Congrès pour toutes les relations internationales. Dans les assemblées générales il sera permis de prononcer le discours dans d'autres langues européennes.

Quant aux communications et aux débats dans les sections du Congrès, ils pourront avoir lieu en français, en allemand et en russe.

22. La personne chargée de présider une séance devra diriger les travaux conformément aux règles admises.

23. Les étudiants en médecine et les personnes étrangères qui s'intéressent aux travaux annoncés pour telle ou telle séance, pourront y être admis par les présidents honoraires, après entente préalable avec les présidents de Comités de Sections.

24. Les communications et les questions concernant les travaux de telle ou telle Section du Congrès devront être envoyées au président du Comité de la Section qu'elles concernent. Toutes les autres communications et questions devront être adressées au Secrétaire général du Congrès.

25. Dans une des assemblées générales on désignera le lieu de réunion du XIII Congrès International de Médecine.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, JANUARY 18, 1896.

A NEW FORMULA FOR CRANIOGRAPHERS.

That the results of craniology thus far have been in great degree negative, is the deliberately expressed opinion of DR. HARRISON ALLEN, and this not very creditable state of affairs he ascribes to the fact that individual characters of both intrinsic and relative importance, have hitherto failed to receive attention. At the meeting of the Association of American Anatomists, recently held at Philadelphia, DR. ALLEN demonstrated a new method of recording the peculiarities of the human skull and proposed the adoption of a formula to be used in the description of every skull, embracing the data contained in the following list of characters: "In the frontal norma observe the glabella and supra-orbital ridges, defining the degree of curvature and of deflection in each. The external angular process of the frontal bone and the degree that it is inclined downward from a horizontal line. The frontal and maxillary portions of nasal bones are each to be separately measured, as well as the convexity of the bone from side to side. The root of the nose is recognized as a separate anatomic quantity; it extends from the fronto-nasal suture to the position of the small foramina on the dorsal aspect of the bone. The bone from the line of these foramina to the free distal border receives the name of the *salient*; the deviation of both the root and the salient to be recorded in degrees from the vertical. The recognition of the pre-maxilla as a constant quantity is important, especially to recognize the nasal aspect of the pre-maxilla as it extends from the incisive foramina to the end of the nasal spine. The length and height of the incisor crest are to be measured and other peculiarities of the pre-maxillary portion of the floor of the nose are to be

noted also. The distance from the border of the anterior nasal aperture to the free border of the alveolar process is to be taken. In the lachrymal bone indicate the union or absence of union between the hamular process and the maxilla; the relations existing between the lachrymal groove and the orbital surface; the length of the suture between the lachrymal bone and the os planum of the ethmoid. Note in the malar bone, whether it does or does not enter into the spheno-maxillary fissure; whether or not there is a process of the posterior surface of the temporal border; whether or not there is a suture trace on the inner side of the zygomatic surface.

"Viewing the skull from beneath and proceeding from behind forward, record the following points: The shape of the hard palate whether parabolic, hyperbolic, or U-shaped; the choanæ, whether or not the lower margin is wider than the upper; the pyramidal process of the palatal bone, measuring its length; the petro-sphenoidal fissure, whether it is over-lapped by the spinous process of the sphenoid, or free therefrom; the foramen lacerum medium, whether it is open throughout, or closed from the basal aspect; the petrosal portion of the temporal bone, whether narrowed or inflated along the median border.

"Turning the skull on the side, the following points are to be observed, passing from before backward, the notch back of the external angular process, its depth and other peculiarities; the temporal ridge, noting the degree of interruption between the frontal and parietal portions at the stephanion; the parietal bone, whether or not a mortice-like process is present on the inferior border of the posterior mastoid crest; the mastoid process of the bone, whether or not marked by vessel-grooves above the line of the mastoid foramen; the lambdoidal suture, whether serrated or harmonic near the asterion.

"The vertical aspect of the skull yields the following points, from before backward; the sagittal suture back of the bregma, whether it is or is not carinated; the curve of the sagittal suture as it joins the angle of the occipital bone, whether it is continuous with the curve of the occipital or exhibits an interruption; and finally, the interval (sconce or skull-roof) between the temporal ridges."

In reviewing the items of this formula, it is noticed that they have been obviously selected because of their contrast to characters possessed by the anthropoid apes and for their value in establishing data for studies of variation in different individuals of the human race. The region of the supra-orbital ridges differs greatly, as is well known, between the higher apes and man, and also in early forms of man as compared with the later forms. The external angular process inclines more abruptly in long, narrow faces than in short broad ones. The entire region of the external nose, from

the fronto-nasal process to the alveolar process, is in DR. ALLEN's opinion, of great value in craniology, especially in defining race. The nose also distinguishes the apes among themselves, and apes from men. The terms that define the shapes of the palate are those which were employed by BROCA; while the peculiarities of the sagittal suture are in general use to distinguish skulls; especially in differentiating the Eskimos from other races and general individual forms of low mental grade from those having a higher degree of mental development. The use of the other characters is original, so far as the lecturer knew, and for them he assumes responsibility. Among the more important of these may be mentioned the size of the spinous process of the sphenoid bone; the degree of closure of the foramen lacerum medium; the shapes of the choanæ; the lengths of the pyramidal process of the palatal bone; the interruption of the temporal ridge at the stephanion, and the changes in the lambdoidal suture as it approaches the asterion.

It is asserted by DR. ALLEN that a skull which is described by the formula above given, could readily be identified, if all labels or other arbitrary means of identification were lost, for, in his judgment, it would be physically impossible for any two skulls to have all the points of the formula the same. It will be observed that no measurements are along lines which convention indorses in describing crania, and nothing is said with regard to cubical capacity. The data embraced under the two heads last-mentioned, are entirely independent of the formula, and it goes without saying that the formula here given supplements rather than supplants them.

TUBERCULOUS BONE DISEASE OF CHILDREN TREATED BY INJECTIONS OF IODOFORM.

DR. WIELAND reports to the *Deutsche Zeitschrift für Chirurgie* that he has come to regard the conservative treatment with a 10 per cent. iodoform injection for tuberculosis of the soft parts, bones and joints, much more satisfactory in children than in adults; and analyzes in support of his view the report of the Children's Hospital at Basel for the last five or six years. He finds that tuberculous abscesses treated in this way healed very often. The method employed was to empty the abscess with an aspirator, then irrigate with a 4 per cent. boric acid solution, and after the cavity had been well washed out to inject 20 to 50 c.c. of a 10 per cent. iodoform emulsion, either in glycerin or oil or in water, adding a small quantity of gum arabic to hold the iodoform in suspension. As often as the abscess refilled the operation was repeated. It is essential to keep the part treated at rest, and to firmly support it with a flannel bandage.

Of twenty-one cases treated in this manner sixteen, or 80 per cent., were fully cured, four were removed from the hospital by parents before treatment was

completed, and one case was a positive failure. In eleven of the sixteen successful cases one injection sufficed; in one, two were necessary; and in four, the patient required three injections. Fistulæ at the point of injection occurred four times, and once there was a septic infection of the large abscess.

Twelve cases of joint tuberculosis were treated in this way. Nine, or 75 per cent., were cured and two cases were much improved. Joint cases required from six to thirteen injections given during a period of two to six months.

Four cases had acute nephritis from the iodoform, which, however, speedily disappeared. In one case there was severe iodoform intoxication, but in this case 20 per cent. emulsion was employed.

SENN,¹ after an exhaustive review of the subject several years previously, came to a similar conclusion, but when does a continental authority quote an American? SENN's summary should be kept in view to fully appreciate the force of this remark (page 278). *Conclusions.*—"1. Parenchymatous and intra-articular injections of safe antibacillary substances are indicated in all subcutaneous tubercular lesions of bones and joints accessible to this treatment. 2. Of all substances so far employed in this method of treatment, iodoform has yielded the best results. 3. The curative effect of iodoform in the treatment of local tuberculosis is due to its antibacillary power and its stimulating action on the healthy tissue adjacent to the tubercular product. 4. A 10 per cent. emulsion in glycerin or pure olive oil is the best form in which this remedy should be administered subcutaneously. 5. The ethereal solution should never be employed, as it is liable to cause necrosis of the tissues overlying the abscess and iodoform intoxication. 6. Tubercular abscesses and joints containing synovial fluid or tubercular pus should always be washed out thoroughly with a 3 to 5 per cent. solution of boric acid before the injection is made. 7. Injections should be made at intervals of one or two weeks, etc.," and then follow other aphorisms pertinent to the subject.

It is thus seen that WIELAND simply repeats substantially the conclusions of SENN, made three years before. The long list of continental surgeons favoring the iodoform treatment is fairly stated by GANGOLPHE,² although that author himself favors the method of LANNELONGUE—by chlorid of zinc. MIC-KULICZ, VERNEUIL, MOSETIG-MOORHOF, BRUNS, KRAUSE, VERCHERÉ, GRYNFELDT, DUPIN, BLAIZOT, MARTY, OLLIER, TRIPIER, TRENDLENBERG, VINCENT, and stoutest partisan of all, KOENIG, are quoted by GANGOLPHE as attesting the efficacy of the injection of iodoform emulsion in joint tuberculosis. KOELISCHER and ALBERT, of Vienna, recommended the acid phosphate of

¹ Tuberculosis of bones and joints, 1892.

² Maladies infectieuses et parasitaires des os, 1891.

calcium, but according to GANGOLPHE, a case of gangrene of the foot, consecutive to this treatment, decided him against the remedy.

In conclusion, it may be stated concerning iodoform emulsion injections as GANGOLPHE said of chlorid of zinc: "It is not a panacea, but a powerfully modifying agent." But our own experience fully justifies the hope of curing 30 per cent. of the less advanced cases of tuberculous joint disease by its use.

CASTRATION OF CERTAIN CLASSES OF CRIMINALS.

At a recent meeting of the Chicago Medico-Legal Society several papers were read on the management of some phases of sexual aberration in criminals and degenerates, that were somewhat noteworthy both from their substance and their authorship. The first was one by DR. F. E. DANIELS, of Texas, advocating castration as a punishment for certain sexual crimes, a proposition that has been before advanced from several different quarters, as well as by his own papers, but which so far has received no general approval. The same subject was taken up or alluded to more or less fully in the communications of DR. HAMILTON D. WEY, of the Elmira reformatory, and MR. MATT. W. PINKERTON, both in their special departments criminologists of national repute, and also by MR. W. S. ELLIOTT, a leading lawyer of Chicago. The general consensus of opinion of the speakers seemed to be against the views of DR. DANIELS, and the legal and constitutional objections to the proposed change in the criminal law were very strongly presented. The subject has, however, a medical side which was also brought out, though more by the lay speakers than by the physicians, and some stress was laid on the injury to character that might be thus produced, a danger that, considering the material thus to be operated on, might seem to the ardent advocates of the procedure as a rather negligible quantity. The possible danger, however, to mental integrity which was less prominently mentioned is a more serious one, and would be of greater weight in a purely medical point of view as regards the constitutional question whether it is or is not to be properly considered an unduly cruel form of punishment. But even here we have to consider whether these criminals are not already mentally as well as morally unsound, and this question arises especially in regard to the senile offenders who make up, as was stated by the legal gentleman in the discussion, a larger proportion of those committed for this form of transgression of the criminal law. The efficiency of the penalty would be doubly dubious in such cases.

If natural developmental impotence is no security against the commission of sexual crime, what guarantee is there that an artificially induced disability will be any more a deterrent? The argument that

by this procedure we prevent the propagation of criminals and degenerates loses its force when it is considered that it is proposed to be applied to only a very limited number of individuals, and those often late in their lives when perhaps all possible mischief has been done. The moral effect as a preventive is undoubtedly overestimated, as any medical man can see from a little consideration is likely to be the case; and leaving all sentiment aside, it would appear that the penalty can be condemned for its probable inefficiency alone. Its proposal, however, bearing in mind the tendencies of lynch law in such cases, might seem prompted by benevolence rather than by cruelty, and as an attempt to divert popular passion rather than to vindictively add to the criminal code such a cruel and unusual punishment as is forbidden by the Constitution or the United States.

The therapeutic value of castration in cases of sexual aberration and perversion, which was especially discussed by DR. WEY, is also very much open to question and its legal bearings are not less important. The reported brilliant results of a Kansas physician with feeble-minded children will hardly, by themselves, suffice to give the operation a good medical standing; certainly not without confirmatory experiences elsewhere. There is moreover a certain amount of testimony by alienists and others that is not in support of his views, at least as regards the operation in the male, and the *a priori* considerations taking every aspect of the subject into account, will be claimed by a large proportion of the profession to be decidedly against them. Even if can be proven a legitimate therapeutic measure and as justifiable as amputation of a limb when it is indicated, there will still be the damaging possibility of legal complications that was very strongly emphasized by DR. WEY in his paper, to affect its popularity. It is not likely to become a common practice with prudent practitioners, and as a recognized therapeutic procedure it can hardly be said to have a brilliant and useful future. In other columns we present an abstract of the meeting.

LIABILITY FOR ACTS OF OTHER PHYSICIANS.

A practicing physician promised a party to attend his wife professionally during her confinement. A short time before that event took place he left the city for a three-days' vacation; having first visited the woman, and made an examination of her condition, from which he concluded, as he informed her, that his services would not be needed for a few days. Before his return, however, she was confined. The husband, when his wife's travail came on, telephoned to the house of this physician for him to come at once; and in response to this message another physician arrived, stating that the first one was out of town, and that he represented him, and proceeded to take charge of the

case, and to deliver the woman of her child, without any objection being made. It was not suggested that his treatment of the wife was unskillful, but in an action brought by the husband to recover damages from the first physician, evidence was offered to show that after the birth of the child the substitute physician improperly severed the umbilical cord so close to its body that it was impossible afterwards to tie it, and that the child consequently died, in a short time, of umbilical hemorrhage. The shock caused by her child's death, it was testified, so affected the mother as to seriously injure her health and render her an invalid for months, thereby depriving the plaintiff of her services and companionship, and making it necessary for him to incur expenses which he would not otherwise have been called upon to meet. The trial judge adopted the theory advanced, that the substitute was the agent and representative in this matter of the first physician, and that, therefore, he was legally liable for such loss of services and companionship, and for such expenses resulting from the second physician's unskillfulness. But the court of errors and appeals of New Jersey holds that this was wrong and reverses a judgment rendered in favor of the husband. (MYERS vs. HOLBORN, decided November 20, 1895.) These were both practicing physicians, having no business connection with one another, except that the second was attending the patient of the first while he was temporarily absent. Even if it be admitted, therefore, that the second was employed by the first to attend upon this woman, the reviewing court holds that that fact did not render the first physician liable for the other's neglect or want of skill in the performance of this service, for an examination of the authorities will show that a party employing a person who follows a distinct and independent occupation of his own is not responsible for the negligent or improper acts of the other. But if it had reached the conclusion that the second physician was the agent of the first in this instance, the court further says that under the New Jersey statute no recovery could have been had in this case, the pecuniary injury sustained being that which resulted from the death of the child causing the sickness of the mother attended by loss of her services and an increase of expense on her account.

THE MEDICAL SOCIETY OF THE DISTRICT.

The Medical Society of the District of Columbia is fortunate in having for its president, Dr. SAMUEL C. BUSEY, whose aims are the highest, and whose activity is not at all diminished by his length of service. The Society has acted wisely in continuing him as president.

In his annual address just published, he takes up the work of the Society during the past year, especially in regard to legislation for the District, and a

complete record is given of the doings of the committee having in charge the various bills to regulate the practice of medicine, in which the many difficulties encountered by the Society are fully dealt with. We regret to say that the Society's recommendations have not yet met the approval of Congress by statutory enactment, although the committee having the matter in charge distinctly informed the Senate that they would be willing to accept for the District any of the medical practice acts in force in forty-one States of the Union.

Concerning the publication of the Society's Transactions, some interesting local history is given, and then the author recommends as a means of advancing the interest of the Society, that an annual volume of Transactions be published. In this recommendation he disclaims any intention of being inimical to the excellent *National Medical Review*.

RULES OF THE XIITH INTERNATIONAL MEDICAL CONGRESS.

We publish in another column the original rules issued for the organization. We are informed by that document that the Congress is placed under the patronage of His Imperial Highness the Grand Duke Serge Alexandrovitch. The Congress will be held at Moscow beginning Aug. 7, (19 old style) 1897 and continuing eight days. Ten rubles (25 francs) is the membership fee. There will be twelve sections. The Organization of the Congress will be under the general direction of the Medical Faculty of the Imperial University of Moscow. The time assigned to the papers will not be allowed to exceed twenty minutes, and there will be only two or three general sessions. French is recognized as the official language of the Congress for all international relations, and other European languages will be permitted in the General Assembly, but communications to the Sections must be made in French, German or Russian. All communications should be addressed to the Secretary General of the Congress, Moscow.

CORRESPONDENCE.

Jeanel's Emulsion—a Correction.

LOUISVILLE, Jan. 13, 1896.

To the Editor:—I regret to note that in spite of my correction of the proof in the formula containing Jeanel's emulsion, the typesetters have persisted in the use of the *ounce* mark instead of the *drachm*. The prescription as originally written and corrected in the proof was as follows:

R Jeanel's emulsion of copaiba ʒii
Distilled water ʒvi

The emulsion is very powerful, and, in the strength you print, it would be quite sufficient to dissolve the corneal epithelium. The matter is so important that I beg you to correct it as soon as possible. I am, sincerely your friend,

DUDLEY S. REYNOLDS.

NOTE.—The corrected proof was not received at the publication office until that portion of the JOURNAL had been printed.

Tribadism.

DUBUQUE, Jan. 10, 1896.

To the Editor:—Referring to your note in reply to Dr. King, in issue of January 4, page 41, would say: I have consulted Thomas' Medical Dictionary, International, Funk and Wagnall's, and American Encyclopædic dictionaries, all I have at my immediate command, for definition of *tribadism*. Believing others beside Dr. King and myself are ignorant of its meaning, will you or the author enlighten us.

Fraternally, J. H. GREENE.

ANSWER.—The term is defined in Dunglison's, Billings', Foster's and Gould's dictionaries, as a form of sexual perversion. By looking at any of these dictionaries you may find the word.

PUBLIC HEALTH.

Smallpox Stamped Out.—The smallpox epidemic at Martin's Ferry, Ohio, appears to be at an end, Wheeling and Bridgeport having raised the quarantine against that city.

Death Rate in Chicago.—The Report of the Bureau of Vital Statistics of Chicago, Ill., shows the following: Total deaths from all causes during the month of December, 1895, 1,771; annual death rate, twelve months ended Dec. 31, 1895, per 1,000 of population, 15.12. The corresponding death rate of year 1894 was 13.36.

New Jersey State Board of Medical Examiners.—Dr. E. L. B. Godfrey, of Camden, N. J., has been elected secretary of this board, *vice* Dr. Wm. Perry Watson, resigned. The next meeting of the board will be held at Trenton, N. J., on the third Tuesday and Wednesday of June next, and applications for examination must be filed with the secretary at least ten days before that time.

Duluth Water Officials Indicted.—Press dispatches from Duluth, Minn., of January 13, state the following: "The reign of the Duluth Gas and Water Company, which caused an epidemic of typhoid fever and many deaths here by furnishing impure water, is at an end. This afternoon the grand jury returned indictments against William Craig, the general manager, and James Stewart, the chief engineer, at the main pumping station. Craig is indicted on a charge of manslaughter in the second degree for the death of Harry W. Smith, caused, it is alleged, by the negligence of Craig, acting as manager of the gas and water company, in furnishing impure and unwholesome water."

Anti-Alcoholic Physiology in the Public Schools.—New York, as well as certain other States, has a law upon the statute books, requiring that the dangers of alcoholic drinks shall be lectured about or taught in the public schools, under the guise of physiology. There has been some rebuke of the educational authorities of New York city because so very little has been done, so that recently the superintendent has been set to work to complete a schedule of lessons to be taught in the balance of the current year. It is reported that teachers intend to apply to the legislature for a repeal of the act that requires such instruction, on the ground that it interferes with more important work.

Homes for Consumptives at Glasgow, Scotland.—The great work, conducted by Mr. Quarrier, for the relief of the orphan children of Glasgow, has nearly closed a quarter century. His homes "handle" not less than 1,000 boys and girls yearly and he now aims to provide a retreat for the orphans and others who develop tuberculosis. About every third child coming under his charge has a hereditary contact with consumption. These children do not fall victims to that disease, he says in his report, "because they were lifted out of the horrible pit and made to stand solid and straight by fresh air, good food, and surroundings that went to make health." He proposed that the

consumptive homes would be constructed on the most scientific principle. In all he would require another £45,000 to build hospital accommodation for 200 patients, each with a separate bedroom. During the year they had taken in 400 additional children, making in all 1,400 dealt with in the twelve months. He thanked all who had helped the work by their gifts and sympathy, and said that as he had got during the past year for all purposes the £28,000 he had desired, so now he required £35,000 for the ensuing year, and expected to get it.

Co-relation Between Meat Inspection and Ocular Cysticercus.—An article in the *London Lancet* for October 19, informs us that in the twenty-fifth *Compte Rendu* of the ophthalmologic clinic of Dr. G. Hirschberg there is fresh evidence of the happy influence of meat inspection on the prevalence of ocular cysticercus in mankind. It appears that, from 1853 to 1866, Von Graefe had met with ninety cases of this affection among 80,000 patients suffering from diseases of the eye. From 1869 to 1885 Dr. Hirschberg examined the eyes of 60,000 people also affected with various eye diseases, and in seventy the cysticercus was discovered. From 1853 to 1885, this form of parasitism was met with in the proportion of 1 in every 1,000 clinic cases, and in certain years, as in 1876, it was 1 in 420; 1 in 450 in 1879; and 1 in 800 in 1877. When the organization of meat inspection was further perfected these proportions were considerably modified in the course of time, but not immediately. For instance, from 1883 to 1885, the cases of ocular cysticercus were still relatively numerous, but in the four following years, between 1886 and 1889, of 30,000 patients at the eye-clinic only one had this entozoön in the ocular cavity; and among 43,000 who came under his observation from 1890 to 1894 there were but two thus affected and they were strangers to the district. These figures go far toward showing that a good system of meat inspection, in suppressing the issue of diseased flesh as a food for man, has at the same time almost completely abolished a rather frequent source of human ocular parasitism.

Law for the Prevention of Milk Typhoid in New Jersey.—A recent bulletin of the State Board of Health of New Jersey states that during the year 1894 an outbreak of typhoid fever occurred in Essex County which could have been arrested after the appearance of the first case, if the local health board had been prepared to act. No suitable action was, however, taken and as a consequence 115 cases of the disease developed in the locality, 107 of these persons having partaken of milk which was produced on the farm where the disease first appeared. Fifteen deaths attended this epidemic.

During its last session, the legislature of that State passed the following act which gives to the State Board of Health an equal authority to proceed, in such emergencies, with the local boards.

"That when the State Board of Health, or any officer thereof, duly authorized in writing by such board to act for or on behalf of said board, shall have reason to believe that any milk has been contaminated by the emanations, exhalations or discharges of any person sick with communicable disease, it shall be lawful for the said State Board of Health, or the officer so authorized to act in the premises, to prohibit the transportation or sale of any milk suspected to be contaminated as aforesaid, and also to prohibit the transportation or sale of any milk which may be produced, stored, kept or found upon any premises infected by such disease: such prohibition shall continue until the State Board of Health, or the officer authorized to act in the premises as aforesaid, shall in writing remove such prohibition.

"That any person or persons who shall transport or sell any milk the sale and transportation of which has been prohibited, pursuant to the provisions of the first section of this act, shall be liable to a penalty of \$50, to be recovered by the State Board of Health in an action upon contract for the uses of the State of New Jersey in any court of record within said State."

This act does not lessen the responsibility of local boards of health, nor in any respect relieve them of the duty of making

and executing ordinances to prevent the spread of disease by milk. It only provides a method whereby the citizens of the State may be protected in cases where local boards fail to take advantage of the privileges accorded them by the laws.

Variable Milk Standards. The following interesting report of a milk-case appears in *Public Health* for November, showing only too clearly how transitional is the situation in England, as to the standardizing of milk. In the number of this JOURNAL for October 26, we referred to views and testimony of Mr. Richard Bannister regarding the fluctuating milk-standards. As will be seen below, his evidence in the case was promptly followed by a dismissal of an otherwise well-supported charge of the local health officials. "In a case heard on September 26, at the Harlesden police court, the Middlesex County analyst Mr. Bevan, working to a standard of three, certified that 10 per cent. of the milk fat had been abstracted. The milk also contained boracic acid. The defendant had his third of the sample analyzed by another analyst, who certified to dilution with 8 per cent. of water, but disagreed as to the removal of milk fat. The same milk was sent to Somerset House (by which is meant that branch of the English local government that has charge of questions of food-adulteration) and a certificate received to the effect that the government chemists were unable to say that fat had been removed." At the hearing, Mr. Richard Bannister, on behalf of the Somerset House chemists, stated that the limit now adopted was 2.75, and that the difference was so small between 2.69 and 2.75 that they could not say any fat had been abstracted; moreover, this year had been a bad season, and they had found the milk fat somewhat lower than usual. The bench, on Mr. Bannister's evidence, dismissed the case. It is generally known that some few years ago the Somerset House chemists never supported an analyst's certificate for fat removal, unless the fat found was under 2.5 per cent.; latterly, as Mr. Bannister says, the limit has been raised to 2.75 per cent. Nothing can show more clearly the great public inconvenience of variable standards than the above case. Mr. Bevan works to a standard of 3; another analyst, as stated in the evidence before the Food Products Adulteration Committee, works to 2.5; the Somerset House chemists "wobble round" 2.75, allowing in practice a few hundredths for differences in season. It is to be hoped that the voluminous evidence taken before the committee of the last parliament will be utilized, added to, and a bill next season brought in, codifying, enlarging, and amending the existing law, and laying down definite standards, so as to render it impossible for any wide divergence of opinion on identical facts to interfere with the administration of the law, and to protect those rapacious dealers who would grind the poor, by selling them adulterated foods.

Tennessee State Board of Health. The Tennessee State Board of Health held its quarterly meeting January 8.

John W. Ross, M.D., of Clarksville, was unanimously nominated to Gov. Turney as member of the board to fill out the unexpired term of the late Dr. Daniel F. Wright. The governor expressed cordial approval of this nomination. That portion of the Secretary's report respecting the importation of smallpox into Tennessee from points in Arkansas and Mississippi was taken up and discussed, Mr. Graves in the chair. Dr. Plunket read from the *Nashville American* of January 5, a special telegram from Memphis as to the action of the conference held at Memphis January 4. In this connection the following resolution, offered by Mr. Graves, was unanimously adopted:

"The attention of this board has been called to a special dispatch from Memphis, under date of January 4, and published in the *Nashville American* of January 5, to the effect that the Tennessee State Board of Health was represented in a conference held in Memphis, January 4, in connection with health

authorities from Arkansas; said telegram indicated that drastic measures were adopted at this conference, and that it was agreed that negroes were to be given to understand that they were to submit to vaccination or be shot; that the white people proposed to take care of their families whose lives were being endangered by the crazy action of negroes. We wish now to state that no such action was had, recommended or even hinted at. Therefore, be it

Resolved, That this board disclaims any connection with any such proceedings, as there were none such had at the conference held at Memphis.

Resolved, Further, that this board condemns and rebukes in strong terms the sending forth of such untrue and sensational telegrams either by the associated press or newspaper correspondents. That the entire action of the meeting is, in fact, embraced and set forth in the communication sent by the members of said conference to the governor of Arkansas and being embraced in the report of the secretary of this board to this meeting.

Dr. Plunket then called attention to the condition of affairs in Arkansas and Mississippi relative to smallpox and offered the following resolution:

WHEREAS, There has existed for some weeks past a number of foci of smallpox among negro settlements located near the Mississippi River, in the State of Arkansas; and,

WHEREAS, For weeks the lives and health of the people living in those counties of Tennessee which form the opposite bank of said river have been placed in constant jeopardy by the practice of surreptitiously passing to and fro of the inhabitants of these infected centers, a number of instances have thus recently occurred in which smallpox was brought into the State by these people and which practice, under ordinary means, is practically impossible to prevent, therefore be it

Resolved, That the Surgeon-General of the United States Marine-Hospital Service be, and is hereby requested to take, without delay, such steps as will give the western boundaries of Tennessee that protection from this pest, which under recent Federal law is provided for the States and which under the circumstances our people are so justly entitled to."

Dr. Elcan offered the following resolution:

WHEREAS, This is the centennial of the admission of Tennessee into the Union; and,

WHEREAS, The State has determined to hold an exposition for the purpose of showing to the world the great resources and varied products of the State, and the progress made in the arts and sciences during this period, and

WHEREAS, The public health service of the State has been and now is an important factor in its development,

Resolved, That the State Board of Health publish a bound volume, to be known as the Centennial Reports of the State Board of Health, showing the climatology and topography of the State, the endemic and epidemic diseases which have prevailed from time to time, together with the origin and history of the State Board of Health, and the benefits derived therefrom by the people of the State, and in order to carry into effect the objects and purposes of this resolution, the President of the board is hereby authorized and instructed to appoint the following special committees, whose duties it shall be to collect and formulate the facts and statistics in the form of reports, to be made to the October session of this board. These reports together with the secretary's reports, then to be compiled by secretary into a bound volume for use by the State.

"Committees 1, The origin and history of the State Board of Health; 2, The endemic and epidemic diseases occurring in the State; 3, The climatology and topography of the State."

Ohio Board of Health. The following is a summary of the tenth annual report of the Ohio State Board of Health for the year ended Oct. 31, 1895:

So far as reports enables us to speak the year seems to have been one of general good health, except at its close, when typhoid fever was more than usually prevalent. We must again deplore the fact that Ohio is without a proper system for the collection of vital statistics, which would enable us to present accurate data showing its healthfulness as compared with other States, and the healthfulness of its cities and towns as compared with one another. Thousands die and thousands are born of whom no official record is made. It is recommended that the laws be changed providing for the registration of births and deaths by boards of health instead of by assessors.

During the year, that is to October 31, smallpox was reported in Ohio as follows: Cincinnati 131 cases, Cleveland 17, Toledo 3, Columbus 2, Mansfield 2, Lima 5, Martin's Ferry 6, Bridgeport 16. Pease township, Belmont county, 7; Gallipolis township, Galia county, 7; Deerfield, 4, Wellington 3, Addyston 2, Westwood 3, Williamsport 2 and Ripley 1, a total of 206 cases. The disease was still prevailing at Bridgeport and Martin's Ferry at the close of the year.

Attention is called to the fact that smallpox is a very expensive disease. "A single case of smallpox in a small village has been known to cost many hundreds of dollars in actual outlay and loss of business, while an epidemic of the disease may bring a community to the verge of bankruptcy."

General vaccination and revaccination are urged as a sure preventive of smallpox, and one which business men, from financial considerations, if from nothing else, should be interested in having enforced. In regard to pollution of public water supplies the board says: "Few if any of our rivers escape sewage pollution, and none of them affords a perfectly satisfactory supply in an unpurified state. Increasing population will soon make it absolutely necessary for the protection of the public health to prevent the pollution of sources of public water supplies, or to require such supplies to be purified by artificial means."

"The experience of thickly-settled Europe teaches that both of these measures will eventually be necessary."

During the year the board acted upon applications for approval of public water supplies for the following places: Canal Dover, Celina, Columbus, Columbiana, Delta, Fostoria, Lebanon, Logan, Lorain, Montpelier, Osborne, Painesville, Port Clinton, Salem, St. Bernard and Wapakoneta. These were all approved excepting Columbus, Lorain, Painesville, Port Clinton, and Salem. Approval for supplies for Lorain and Port Clinton was withheld pending further investigation.

The question of a new water supply for Columbus is considered and it is said: "The typhoid fever death rate in Columbus for the past eight years shows conclusively that a contaminated water supply is being used. During that period 415 deaths have occurred in that city from this disease, which is equal to 3.86 per cent., of the deaths from all causes. This is a higher rate on that basis than that of any other large city in the State. Columbus can not hope to escape being scourged with this disease until a purer water supply is introduced, and polluted wells, wherever found, are closed."

The board acted upon applications from the following places for approval of sewerage systems: Ashland, Cincinnati, Cleveland, Delaware, Evanston, Hamilton, Logan, Marysville, Tippecanoe City, Warren and Wyoming. Approval was refused in the case of Cincinnati and Cleveland. These sewerage system of Ashland, already in use, was condemned. In most instances approval was granted on condition that the sewerage be properly purified within a reasonable but specified time.

Attention is called to the gross pollution of streams by sewage at Bucyrus, Tiffin, Findlay, Mansfield and Lima; also to the pollution of streams by waste from strawboard works. The enactment of proper laws to deal with these rapidly-growing evils is urged. Special reports are given of inspections of several public building and of investigations of nuisances arising from various causes. There are now 1,738 local boards of health in the State, all of them in close communication with the State board. "While in many places the duties of a board of health are greatly neglected, as a rule excellent work is being done by these local organizations. Homes have been made healthier and happier, the ravages of contagious diseases greatly lessened, and the public health measurably improved by their efforts."

Six counties of Eastern Ohio sent delegates to a conference with the Ohio State Board of Health, January 8, at Bellaire. About sixty were present.—Localized epidemics of measles are reported from Union, S. C., Coopersdale, Lambertville and Titusville, Pa., and Port Morris, N. J.

Health Reports.—The following health reports have been received in the office of the Supervising Surgeon-General Marine-Hospital Service:

SMALLPOX—UNITED STATES.

Louisiana: New Orleans, December 1 to January 4, 10 deaths. Michigan: Detroit, smallpox reported present December 28 to January 4.

New York: Brooklyn, January 4 to 11, 2 cases, 1 death.

Tennessee: Memphis: January 4 to 11, 7 cases.

SMALLPOX—FOREIGN.

Dublin, December 14 to 28, 2 cases, 2 deaths.

Hong Kong, November 16 to 23, 1 death.

London, December 21 to 28, 1 death.

Madrid, December 17 to 24, 7 deaths.

Montevideo, December 1 to 7, 4 cases.

Naples, December 18 to 25, 10 cases, 10 deaths.

Odessa, December 14 to 21, 7 cases, 1 death.

Prague, December 14 to 21, 26 cases.

Rio de Janeiro, November 23 to 30, 36 deaths.

Rotterdam, December 21 to 28, 1 case.

St. Petersburg, December 14 to 21, 8 cases, 7 deaths.

Warsaw, December 7 to 21, 4 deaths.

CHOLERA—FOREIGN.

Austria-Hungary: Galicia, December 10 to 16, 11 cases, 7 deaths; from Aug. 23 to Dec. 16, 1895, in 56 localities, a total of 424 cases, 278 deaths.

Egypt: Borachia, December 4 to 5, 2 cases, 2 deaths; Cairo, December 7 to 11, 1 case, 2 deaths; Damietta, December 5 to 11, 16 cases, 17 deaths; Farascour, December 8 to 10, 10 cases, 13 deaths; Matarieh, December 8, 1 case, 1 death; Zarka, December 7 to 9, 5 cases, 4 deaths.

CHOLERINA.

Morocco: Stellen, December 15, 13 deaths.

Russia: St. Petersburg, December 14 to 21, 68 cases, 44 deaths.

Turkey: Constantinople, December 17 to 23, 2 deaths.

YELLOW FEVER—FOREIGN.

Brazil: Rio de Janeiro, November 23 to 30, 18 deaths.

Cuba: Santiago, December 21 to 28, 12 deaths.

NECROLOGY.

JAMES EDMUND REEVES.—The following is a brief biographical sketch of the late James E. Reeves, notice of whose death appeared in the JOURNAL January 11. James Edmund Reeves, Chattanooga, Tenn., son of the Rev. Josiah Washington and Nancy Mosee (Kemper) Reeves, grandson of Thomas Washington Reeves, was born April 5, 1829, Amissville, Rappahannock County, Va. Obligated to assist his father, who was a tailor, his early education was neglected, and he had to leave school at the age of 14; but he was determined to gain more knowledge, and by extra work made money with which to purchase books. At the age of 19 he commenced the study of medicine with Dr. Elam D. Talbott, at Philippi, Va., and after one year's instruction under this preceptor, he went to New Market, Va., and became the pupil of Dr. Jacob Neff. Here he was given every possible opportunity to study disease at the bedside, and frequently had charge of patients. In the spring of 1850 he opened an office at Sutton, the county seat of Braxton County, now West Virginia, and by the following October had earned enough money from his practice to enable him to attend a course of lectures at Hampden Sydney Medical College, Richmond, Va. His second course of medical lectures was at the University of Pennsylvania, and he was graduated from that institution in 1860. He remained one year at Braxton Court House, after that nine years at Philippi, seven years at Fairmount, twenty years at Wheeling, W. Va., and for the past five years and a half at Chattanooga, Tenn. Soon after settling at Wheeling he began to agitate the subject of municipal hygiene, and secured the passage of an ordinance establishing a city health department. In 1869 he was elected city health officer and county physician, which office he held four years. Subsequently he was elected a member of the city council, and served four years. He was one of the founders of the American Pub-

lie Health Association, of which he was president in 1885. In 1867 he prepared and sent out the call for the establishment of the State Medical Society, of West Virginia, and was elected its first secretary, and in 1881 chosen its president. He was one of the executive committee, for West Virginia, of the International Medical Congress, in Philadelphia, 1876. In 1882 he was elected a member of the Judicial Council of the AMERICAN MEDICAL ASSOCIATION. In 1884 he was elected an honorary member of the Connecticut State Medical Society. For many years he has been a corresponding member of the Pathological Society of Philadelphia, was one of the vice-presidents of the Section of Public and International Hygiene of the International Medical Congress, Washington, D. C., 1887; vice-president of the American Microscopical Society, 1886; member of Advisory Council Pan-American Medical Congress, also Demonstrator of Pathological Histology, at the meeting in Washington, September, 1893. He was a member of the Association of American Physicians, was the author of the law creating State board of health of West Virginia, of which he was a member, and its secretary for five years. He was employed by the State board of health of Tennessee to make sanitary inspections of the State's defences against yellow fever during the Jacksonville epidemic of 1888. He was particularly interested in microscopic investigations, and has devised sundry microscopic appliances.—*Physicians and Surgeons of America.*

MICHAEL ALOYSIUS CREMIN, M.D., a long time resident of New Haven, Conn., died December 28. He was a graduate in arts, and an alumnus of the College of Physicians and Surgeons, New York class of 1875. He was a licentiate in midwifery from the Royal Rotunda Hospital, Dublin. He had been prominent in municipal and educational circles in New Haven, Conn. The cause of death was ascribed to neurasthenia. He left a widow and family; his age was 43 years.

GEORGE HENRY KIRWAN, M.D., of Wilkes Barre, Pa., who died December 28, aged 41 years, was one of the prominent practitioners of the Wyoming valley. He received his degree in 1882 from the College of Physicians and Surgeons, New York. He had been United States Examining Surgeon and attending surgeon at the Luzerne County prison. He died at his home without a rally from an operation done for relief from an attack of appendicitis.

M. N. BARBER, M.D., of Milwaukee, Wis., January 6, aged 75.—Oliver A. Dailey, M.D., of Kansas City, Mo. January 5, —G. Weston Wood, M.D., of Minneapolis, Minn., January 6, aged 53.—A. N. Barrows, M.D., of Hartford, Conn., January 3, aged 79.—Thomas H. Moss, M.D., of Hartford, Mo., December 25, aged 64.—R. Elliott, M.D., of Knoxville, Iowa, January 8.—J. A. Throckmorton, M.D., of Houston, Tex., December 28, aged 75.—H. R. Payne, M.D., of Kansas City, Mo., December 29, aged 68.—G. B. Lathrop, M.D., of Ann Arbor, Mich., December 31, at Los Angeles, Cal.—Jonathan Morris, M.D., of Ironton, Ohio, Dec. 26, 1895, of cerebral hemorrhage, aged 72. He graduated from the Cleveland Medical College in 1847, and had been in active practice ever since that time, serving three years in the U. S. Army as surgeon of the Ninth Virginia Volunteers. He has also been honored with many responsible and honorable positions, among which was representative from the county of Lawrence in the Ohio legislature. He has been a member of the AMERICAN MEDICAL ASSOCIATION for many years, and almost always in attendance at its annual meetings.

MISCELLANY.

John R. Park, M.D., is Superintendent of Public Instruction in the new State of Utah.

Portrait of Dr. Peck.—The many friends of the late W. F. Peck, M.D., will be pleased to learn that a life-sized painting of the distinguished Iowa surgeon will be placed in the historical rooms at the capitol in Des Moines.

Asepsin is the name of a new "cure" for consumption, which the daily press informs us will soon be made public through the columns of an Eastern medical journal.

Transactions XI International Medical Congress.—Perhaps some of our readers can inform us for the benefit of numerous correspondents when the volumes will be ready for distribution.

A Royal Physician.—The Queen of Portugal has just passed the examinations qualifying her for practice as a physician in the land of her adoption. It is the first instance on record of a lady of sovereign rank winning for herself by means of diligent study the diploma of a Doctor of Medicine.

New Medical Journals.—We have received the following new journals: *Lailysdale's Lancet*, edited by John M. Langsdale, M.D., and published at Kansas City, Mo.; *Cleveland Journal of Medicine*, the official journal of the Cleveland Medical Society, edited by Henry S. Upson, M.D., and P. Maxwell Foshay, M.D. We wish the new journals success and prosperity.

English "as She Is Wrote." Dr. Willis P. King, the Secretary of the Missouri State Board of Health, is said to have received the following:

"*Deer Docktur:*—Ples informe me when and whar the State Bord of Helth Meats."

Another interesting correspondent wrote him of a successful operation he had performed on a case of "pendasetas."

Measure of Damages Effected by Miscarriage.—In the personal injury case of Tunncliffe v. Bay Cities Consol. Ry. Co., decided by the Supreme Court of Michigan, Dec. 10, 1895, it holds that if the plaintiff was entitled to a verdict, she had the right to damages for personal pain and suffering, mental and physical, occasioned by the accident, and, if her sickness was aggravated by a miscarriage caused thereby, the attendant pain and suffering were to be considered.

The Livingstone Medical College, London.—This missionary preparatory college has taken up new and more commodious quarters, and are now to be found in East London on Hamfrith Street, Stratford. Dr. Harford Battersby, who has charge of the work, states that in addition to the ordinary lectures on medical and surgical subjects, a special point is made of detailed instruction in the diseases of tropical climates, and lectures are given by those who have been in India, China and Africa respectively.

Reported Suicide of a Faith Healer, following a Failure to Cure.—A dispatch from Rochester, N. Y., informs us that a female healer hanged herself from an apple tree. She was a resident of East Wayland and was the leader of a band of Christian Scientists, or something of that sort. Having been called in to heal a case of meningitis, and having failed, the parents of the patient drove the band out of their house. This failure worried the leading healer to that extent that she threatened to drown herself. She was watched, however, and that mode of self-destruction was prevented, but she managed to elude the watchers so far as to get away and hang herself. This is a very regrettable incident from every point of view, but it is wonderful that there have not been more of the same kind.

Death of a Yellow-Fever Volunteer of 1878.—Robert S. Blakesley, one of the volunteers from New York in the time of the yellow fever plague of Memphis, in 1878, died on Thursday, December 26, after a lingering illness.

Mr. Blakesley was one of the volunteer nurses who went to Memphis in the autumn of 1878, under the leadership of Dr. Thomas S. Easton. The queen city was then in the throes of a serious epidemic. Such of its citizens as could had fled the place, and the remainder were dying daily by scores. Barely enough remained to nurse the sick and bury the dead. A call for help was sent out, and Mr. Blakesley was one of the first to respond. He contracted the fever while on duty, but recovered and returned to his work. He had many thrilling experi-

ences, and some of them were published upon his return. He brought back a gold medal bearing this inscription: "For bravery. Presented to Robert S. Blakesley, for heroic conduct during the yellow fever epidemic of 1878."

Once More a Librarian.—From New York comes the report that Dr. John S. Billings, U. S. A., retired, director of the department of hygiene of the University of Pennsylvania, has accepted the position of chief librarian of the consolidated libraries of New York City, consisting of the Astor, Lenox and Tilden libraries. This offer was made a week ago, and Dr. Billings hesitated about accepting it lest he might inconvenience the trustees of the University. They, however, did not wish to stand in the way of Dr. Billings' advancement, and ordered him to accept the offer. In his letter of acceptance Dr. Billings says that until July 1 he will divide his time between Philadelphia and New York, spending two days of every week in each city. Dr. Billings' reputation as an authority on hospital construction is of the first order, and he is the leading authority the world over in medical bibliography. The two works that gave him the greatest fame were his catalogue of the Surgeon-General's library of 90,000 volumes, and the *Index Medicus*. He is considered the best bibliographer in America, and on the strength of that reputation he was elected a member of the National Academy of Sciences.

The Itinerant Practitioner Not a Vender of Drugs.—The Iowa law requires "any itinerant vender of any drug, nostrum, ointment, or appliance of any kind intended for the treatment of diseases or injury, who shall by writing or printing or any other method publicly profess to cure diseases or injury or deformity by any drug, nostrum, manipulation, or any other expedient" to pay a license of \$100 a year. A practicing physician, whose residence is in Ottumwa, Iowa, advertised in two newspapers that he would be at a certain hotel in Oskaloosa, Iowa, every Tuesday for the purpose of treating patients. That he "made a specialty" of chronic diseases and rupture, and that he would treat catarrh of the nose, throat, and lungs in a most successful manner. He also mentioned other diseases which he would treat, such as chronic stomach troubles, liver, kidney and kindred diseases. It was conceded that he was not a vender in a criminal sense, but it was claimed that he vended medicine in a professional sense. The facts showed that he undertook to effect cures for a named consideration, and, like many other physicians, he did not write prescriptions to be put up at drug stores, but used his own medicines. By so doing, the supreme court of Iowa holds, in the case of State vs. Bonham, decided December 10, 1895, he was not a traveling or itinerant vender of drugs, nostrums, or ointments, or anything else prohibited by statute. The law which the prosecution invoked for his punishment, it declares, was not intended to designate the regular medical practitioner an itinerant vender. The purpose was to tax such itinerant venders as go from place to place advertising and selling proprietary medicines, such as "Wizard Oil" and the like.

Care Required of Druggists.—In view of the dire consequences that may result from the least inattention or want of skill, the appellate court of Indiana says that druggists, apothecaries, and all persons engaged in manufacturing, compounding, or vending drugs should not only be required to be skillful, but should also be exceedingly cautious and prudent. All persons who deal with deadly poisons, noxious and dangerous substances, are held to a strict accountability. The highest degree of care known to practical men must be used to prevent injury from the use of drugs and poisons. It is for these reasons that a druggist is held to a special degree of responsibility. The care required must be commensurate with the danger involved. The skill employed must correspond with that superior knowledge of the business which the law requires. Following this expression of opinion, the court holds, in the

case of *Howes v. Rose*, decided Nov. 26, 1895, that where wholesale druggists furnish a retailer the wrong drug, as for example a package of tartaric acid for Rochelle salts, the same being labeled "Rochelle salts," which the retailer opens, puts into a jar and therefrom deals out a small quantity of, as Rochelle salts, to a customer, that although the wholesale dealers, or those who improperly labeled the drug may be liable to the consumer injured thereby, an action will lie against the retailer providing he has been guilty of any negligence in making the sale. But it holds that the mere sale of the wrong drug under such circumstances as those stated does not establish a presumptive case. The facts constituting the negligence must be established before the plaintiff can have judgment.

Anæmia or Anemia?—To the Editors of *The Lancet*: SIRs.—Spelling is, at the present time, a prominent subject. It has a special interest for us now that so many medical books printed in the United States, present to us spelling which we are not yet sufficiently familiar with to appreciate. The readers of *The Lancet* may be interested in the following letter from Professor Skeat, which he has been so good as to give me permission to send to you. The spelling of the word "anemia" carries with it that of many others.

I am, Sirs, yours faithfully, W. R. GOWERS.

"DEAR SIR.—It is quite impossible to regulate spelling. The one great principle in all cases of doubt and dispute is that every man shall make his own laws, and it is not likely that argument will be listened to or even permitted. In the new English Dictionary the spelling given is *anæmia*; all the same, the spelling *anemia* occurs in one of the examples. It is largely a question of date. The Latin *x* became *e* in French; and when words come into English through French the spelling *e* may easily prevail. For example, we have the word *primal* on a French model. I am trying to introduce the spelling *medieval*, to pair off with this; and I think it is making some headway. We have, in Cambridge, a 'Medieval and Modern Languages Tripos.' The practical objection to *x* and *e* is that they are difficult to write and print. In many cases an *e* would serve the purpose. I need not say that the authorized version of the English Bible (by many considered as good authority) has the form *emerods* instead of *hemorrhoids*; yet no one objects. Ogilvie's Dictionary prefers *hemorrhoids* to *hemorrhoids*, and, I think, with reason. There is no *x* or *e* in English; it is always pronounced as *e*, and might just as well be so written. The use of writing is to represent the sound of the words, not to be everlastingly harping upon the Greek and Latin forms. But few people can see this; and when a thing is wrong they stick to it all the same. Thus *aneurism* is common, and I like it and admit it. But it is false etymology; of course it should be *aneurysm*. And the question for those who defend *hemorrhage* is, Will you, then, undertake to use the form *aneurysm*? If not, why not? I pause for a reply. No one now writes *eclestial*, yet it from the Latin *ecclum*. Again I ask, why not?"

Yours sincerely, (Sd.) W. W. SKEAT."

Cambridge, Dec. 15, 1895.

—*London Lancet*, Jan. 4, 1896.

"A Good Physician is Like a Good Statesman."—One of the quaintest of the episodes growing out of the late war between China and Japan has been the gratitude of Prince Li to his surgeon by whom he was treated at Shemonosaki, after the prince had been shot by a fanatic. After the wounding, a celebrated Japanese surgeon, Dr. Kitasato, was immediately sent by the Emperor of Japan to look after the aged and unfortunate statesman. Dr. Kitasato is a great scholar and one of the most distinguished pupils and followers of the late Pasteur. He took the greatest interest in his distinguished patient, and cared for him nights and days, with the result that Li Hung Chang soon recovered his health. The two men learned to admire and respect each other, and a true and sound friendship now exists between them. The Emperor of China and Li Hung Chang having forwarded some very valuable presents to Dr. Kitasato; the latter sent a letter of thanks, to which the great Chinese statesman has just made the following interesting answer:

"Dear Friend:—When I was wounded at Shemonosaki you were so good as to visit me, and by your exceptional skill to

cure me of my injury. Such was your proficiency in your art that I was surprised to see my wound heal in a little more than ten days. My gratitude to you is so profound that words can not adequately express it.

"You have now placed me under a fresh obligation by favoring me with an epistle overflowing with sentiments of the warmest friendship. In it you acknowledge the receipt of the things forwarded to you through the kindness of Plenipotentiary Ito. Out of respect to my imperial master you have been so kind as to say that these trifling presents will be preserved by you as a treasure. At the same time you are pleased to express thanks to me, which I do not at all deserve. Since my return home I have kept very quiet and my health and spirits have steadily improved, so they are now in a normal condition. Even a rainy season lasting fully a month did not produce the slightest pain in the part where I was wounded.

"Your country abounds with good physicians, but a proficient like yourself is not only too rarely found in the East, but also is equal to any even in the West. A good physician is like a good statesman, for it is the aim of both to alleviate the miseries of earthly existence. Let me hope with you that peace and tranquility may last forever, and that people may be spared from sickness and wound alike. Do not believe that in expressing this hope any selfish motives enter my mind."

Li Hung Chang asserts that he never forgets an enemy nor a friend. His letter certainly seems to justify this statement.

Massachusetts Hospital for Epileptics.—There has been established by law, in Massachusetts, at Monson, on premises previously occupied by the State Primary School, a State hospital to be known as the Massachusetts Hospital for Epileptics. Its government is vested in a board of seven trustees appointed and commissioned by the Governor, with the advice and consent of the council, five of whom shall be men and two of whom shall be women, their term of office to be five years, except in the case of some of the first appointees. This board shall appoint a physician and assistant physicians and such other officers and agents as they shall deem necessary, who shall respectively hold and perform the duties pertaining to their offices and agencies during the pleasure of the board. Provision is to be made for the residence of 200 patients. The trustees are to have the same powers and are to perform the same duties in the management of this hospital as are vested in and required of the trustees of the various State lunatic hospitals. After the establishment of the hospital, they are to receive no compensation for services, though they are to be re-imbursed for expenses incurred in the performance of official duty. They may receive into the hospital for care and treatment any adult person, not a criminal, who is subject to epilepsy, provided such person be neither an idiot, an inebriate or violently insane. They may also receive and detain in the hospital, as a boarder and patient, any person subject to epilepsy who is desirous of submitting himself to treatment and makes written application therefor, but whose mental condition is not such as to render it legal to grant a certificate of insanity in his case; but no such person shall be detained more than three months after having given written notice of his intention or desire to leave the hospital. Otherwise, the provisions of law consistent with the act establishing this hospital, applicable to the State lunatic hospitals, regarding the commitment, detention, transfer and discharge of insane patients, are made applicable to this hospital. When any patient is received at this hospital, the superintendent shall report the particulars of the case to the State Board of Lunacy and Charity, which may investigate the same. Epileptic inmates of the class first mentioned who have been committed to any lunatic asylum may be transferred by the State Board of Lunacy and Charity to this hospital, and when that board has reason to believe that any such epileptic confined in any almshouse or other place is deprived of proper treatment or care, whether such epileptic is a public charge or otherwise, it may cause the transfer or commitment of such person to this hospital, and the board shall transfer from this hospital to some State lunatic hospital or asylum such inmates as may be found to be violently insane and requiring treatment therein.

The charges for the support of the inmates of this hospital as are of sufficient ability to pay for the same, or have persons or kindred bound by law to maintain them, shall be paid by such inmates, such persons, or such kindred at a rate to be determined by the trustees of the hospital. The charges for the support of other inmates shall be paid by their places of settlement or by the commonwealth, at the rate provided by law for the support of patients in the State lunatic hospitals.

Practical Notes.

Availability of Acetanilid in Country Practice.—According to the *Virginia Medical Monthly*, Dr. Ben. H. Brodnax, of Brodnax, La., has found that for "that tired feeling," a pinch of acetanilid put into the mouth, mixed with saliva and swallowed, rests you up in a few minutes, so that you are as fresh as before. For headache from fatigue repeat the above and be relieved. As a dusting powder on burns, or as a surgical dressing, or to use on the "cord" at birth, make a mixture as follows: Acetanilid, boric acid, equal parts powder, dust thickly over the surface, covered with a light pad of absorbent cotton. This acts locally as an anesthetic, and is clean. It deodorizes and relieves pain. For intertrigo on infants or adults, use the above, dusting on and separating the surfaces that rub with absorbent cotton. The same as an ointment with castor oil, is a great soothing to painful surfaces, abscesses, etc. For abrasions of the skin caused by a blow from a hard substance, use as above, or mixed with castor oil. On old sores, use by dusting on thick, then cotton, with bandage. During labor it eases pain and brings on profuse sweat, which helps to relax muscular rigidity.

Urticaria Treated by Friction with Salt.—Dr. Meynet, in the *Revue de Médecine et de Chirurgie* advises the treatment of urticaria by frictions with salt. He says that in order to quell the troublesome itching resulting from the urticarial lesions, he has been led to follow a simple measure, but one which, in his hands, has proved the most successful: The wheals are moistened with cold water and rubbed for ten to fifteen seconds with a few grains of kitchen salt, which adhere to the previously moistened pulp of the index finger. One feels at first a slight burning, followed promptly by an agreeable sensation of coolness, and a notable diminution or even cessation of the itching, after which the papules usually disappear rapidly. Upon the area thus treated, one may then apply a little oxid of zinc ointment or rice or almond powder. If the urticaria is extensive, it is better, in order to avoid too much irritation of the skin, to apply the salt frictions to successive portions and not over the whole surface at one time. It goes without saying that one should not neglect the necessary modifications of the diet, and, if the urticaria be of toxic origin, a purgative should be prescribed, the best of which is calomel. Luke-warm baths may also prove useful.

Mercurial Polynceritis. R. V. Engel (*Prager Med. Wochenschrift*, 1894, No. 607) describes the case of a 29-year-old wife, who had manifested for four months typical luetic symptoms. She was treated with mercurial inunctions and in the course of the treatment some 20 grammes of unguentum cinereum were used up. The local symptoms of the secondary syphilis subsided rapidly during the inunctions, but suddenly nervous disturbances appeared which became more and more intense and consisted of motor paresis in the extremities, abducens paresis, marked diminution of the sensation especially as regards touch and temperature, abolition of reflexes and pronounced ataxia. These symptoms could be interpreted only as due to a multiple peripheral neuritis, which was at first ascribed to the syphilis. The inunctions were consequently continued and 14 grammes more of unguentum cinereum were consumed. The nervous symptoms did not subside, however, except the abducens paresis. In the meantime Leyden's decisive contribution concerning the rare causation of neuritis by

mercury appeared and this led to the abandonment of the inunctions, and then the patient improved quite rapidly, and expectative treatment was followed with a complete disappearance of all the disturbances on part of the nervous system.

Cystic Tumor of Breast Recurring on the Opposite Side.—Dr. Herbert L. Snow, of London, writes to the *Lancet* regarding the occasional experience observed in cystic degeneration of the mamma, showing that that disease has a tendency to recur, or repeat itself, in the second or opposite breast. He has seen three cases that have led him to be guarded in the matter of progress. He says: "It is best when operating carefully to remove the whole breast tissue, and if questioned, as commonly happens, about possible 'recurrence' to give a guarded prognosis so far as concerns the remaining organ. The point that we have here to deal with, a general and not merely a local lesion of the parenchyma, is hardly, I think, sufficiently appreciated by the profession at large, but unless attended to may involve the practitioner in some dispute. The first case was that of a woman aged 48, married, with two children, who was admitted to hospital in October, 1894, with an induration at the root of the right nipple of one year's duration. She complained of some lancinating pain. There had been no injury, but chronic ill health, and latterly she had been unfortunate in business. The tumor appeared as large as a hazel nut. The patient thought there had been discharge from the nipple. There was no gland enlargement. Upon removal it was found to be one large cyst, with the remaining parenchyma pervaded by minute cysts; there were no vegetations and no malignant indications. The patient has, about three months since, had the left breast removed for an exactly similar condition, the right side remaining healthy. The second case was that of a woman aged 35, single, seen in 1892. She was a spare, neurotic woman with a fluctuating tumor in the left breast, which had been noticed six weeks, as large as a pigeon's egg. On removal one large cyst filled with turbid fluid was found: the whole breast tissue was filled with tiny cysts. In July, 1893, the remaining organ was found to be slightly lumpy. In August, 1895, a distinct cyst the size of a bean was apparent in the lower segment, and removal was advised. The third case was that of a widow, aged 46, who had three children: she was seen in November, 1893. In the right breast was a large, prominent, globular tumor the size of a hen's egg, freely movable, hard and solid to the touch. The patient was neurotic through much worry. On removal a multilocular cyst with solid, round fibroma as large as a marble was found. There was no malignant tissue. The patient reappeared in July, 1895, with a tumor the size of a walnut, rounded and hard, in the left mamma. It quickly increased in size from augmentation of the fluid contents, and has just been removed, proving wholly cystic.

"Malaria" a Misnomer.—In the *Medical Bulletin*, November, Dr. Irving H. Bachman presents a summary of his studies in paludal disease. According to his view of the case the word "malaria" should be discarded as misleading, and we should adopt the word "malaqua." His remarks include the following propositions:

"The impression that malaria is caused by purely atmospheric influences has become so fixed in our minds that, unless we come in actual contact with the evidence produced in the use of pure water as against that heretofore used, the physician will, in all probability, be very slow to allow himself to be convinced that the word malaria (*mal*, bad; *aria*, air) is a misnomer, and that malaqua (*mal*, bad; *aqua*, water) is the word that should be used to cover the pernicious effects known under the name of malarial fever.

"The germ, which is of soil origin, is strictly a protozoön and reaches its highest development in low, moist ground with a favorable temperature. Surrounded by the proper soil conditions, this protozoön passes from one stage of life into another with considerable rapidity; so that in the present state of our experimental knowledge it is impossible to identify it, nor is it

probable that by culture we shall be able to produce the accepted Laveran germ outside of the human system.

"As a rule, the potable water from the malarial districts is derived from driven wells not over twenty-two feet deep, in soil with clay or some other impervious substrata, which water is generally cool and palatable, often sparkling clear, but more frequently a little turbid. This water is filled with an incalculable number of these germs in all stages of development, and if used as a potable water they naturally find their way into the system through the alimentary channel. This protozoön passes through so many forms or stages of life that in some stages it is light enough to float and be transported by the moist air of low grounds, but in this state it is comparatively harmless except under most extraordinary conditions; it is not until the surface water is used that the real mischief begins, when, by reason of higher development, it has become much more virulent than that floating in the air. A very short period of incubation is sufficient to develop a severe case of malarial fever in the new-comer who uses the surface water.

"From personal observation I know that the exclusive use of pure, deep-seated water affords entire immunity against malaria in sections of country where no white man dared live using the surface water. Nor must it be understood that the exclusive use of pure water simply fortifies and strengthens the system against the attack of the germ. The water is the primary cause of infection, which acts as the direct carrier of the germ into the system through the intestinal tract."

Cocainization of the Nasal Mucous Membrane Before and During Surgical Anesthesia. Dr. Gerster concludes a study of 100 cases of anesthesia in which the nasal mucous membrane was cocainized before and during administration of the anesthetic somewhat as follows:

As a result of the observations made in the 100 cases of anesthesia serving as a basis for the study, it was found that the cocainization of the nasal mucous membrane preceding and during surgical anesthesia, considerably diminishes the distress and oppression felt by the patient at the beginning. There was among the cases recorded that of a physician, who had been etherized before, and to whom the process then was extremely disagreeable. This time, his sense of smell being dulled, he experienced no feeling of suffocation, no tickling or irritation inviting coughing or retching, and his judgment was, that the new process was certainly a great improvement over older methods. In this as well as in almost all the other cases, excepting those of confirmed alcoholics, the observation was made that, at the beginning of narcosis, the patients manifested less reflex irritation than usual; that they entered insensibility more rapidly and quickly, with less struggling, coughing and nausea; that, especially when ether was used, the mask could be approached to the face of the patient much quicker without opposition or resistance. In conformity with this the later stages of anesthesia were also more quiet and more free from disturbing interruptions than usual. But here again habitual alcoholics formed an exception. On the other hand, perhaps ten times, and in about from twenty to twenty-five minutes after the first application of cocain, with no external reason, such as, for instance, profuse hemorrhage, a marked acceleration of the pulse rate, with facial pallor, was observed, followed by profuse sweating, probably the effect of cocain. It seemed also, that cocain anesthesia of the mucous membrane tended to diminish the depth of the respiration. As to the after effects, the impression was that in the cases observed there have been less nausea, vomiting, headache and general malaise than is the rule in ordinary anesthesia. It must be said, however, that in a few instances patients, who did not vomit at all during the first twenty-four or forty-eight hours, vomited a great deal on the second and third day without any recognizable cause. As to the anesthesia of alcoholics, where there is much need of improvements, Rosenberg's method does not afford any marked advantage over older methods. On the whole, it is safe to conclude that in view of the ease and simplicity of the procedure, of the absence of apparent risk, and on account of the undeniable elimination of the trying subjective effects upon the patient caused by the use of cocain

upon the nasal mucous membrane, its extended and systematic trial deserves encouragement.

Hospital Notes.

FIRE AT THE NEW YORK CONTAGIOUS DISEASE HOSPITAL ON RANDALL'S ISLAND.—A fire recently occurred on Randall's Island, New York City, in one of the cheap frame structures, furnished by the now extinct commission of charities for that city. The fire started at an early hour in the morning in a kind of cottage for the isolation of cases of measles: the inmates being two infant patients and one nurse. The nurse acted with great presence of mind and got the two children out of the place without accident. The building was soon completely burned down: loss estimated at \$300, inclusive of the alcohol lamp that did the damage.

THE ANNUAL REPORT of the Connecticut Hospital for the Insane has been filed. The report shows there were 1,683 patients Sept. 30, 1895, 886 of whom were women classified as follows: Town paupers, 935; indigent, 591; State paupers, 104; private patients 27; old soldiers, 26. The percentage of recovery of those admitted during the year was 18.42. Twenty-five insane convicts were admitted from the State prison during the year, of whom two died, two escaped, one was pardoned and ten were returned as cured. There are forty-two insane convicts in the institution, the terms of nine of whom have expired. It cost \$289,857 to run the institution last year, including the new building, North hospital.

AT A MEETING of the Board of managers of the Chester County Hospital, at Chester, Pa., on behalf of Mrs. S. T. Johnson of Philadelphia, a check for \$3,500 was presented to that institution. This lady has already given \$2,500 to the same hospital.—The annual meeting of the board of trustees of the New York State Hospital was held in Binghamton, N. Y., January 7.—At a meeting of the trustees of the Epworth Hospital at South Bend, Ind., plans were perfected for raising the sum of \$20,000 for the purpose of erecting a new building.—The annual election of officers of the Erie County Hospital medical staff was held in Buffalo, N. Y., January 6. The officers of last year were re-elected.

Society Notes.

THE CENTRAL OHIO MEDICAL SOCIETY held its regular monthly meeting at Columbus, Ohio, January 2.—The Kansas City, Mo., Medical Society held a regular meeting January 4. The following officers were elected: President, J. H. Thompson; Vice-President, C. A. Ritter; Secretary, J. W. Kyger.—The Jasper County, Mo., Medical Society held a regular meeting in Joplin, January 7.—The annual meeting of the Schuylkill County Medical Society was held in Pottsville, Pa., January 7. The following officers were elected for the ensuing year: President, A. P. Carr, of St. Clair; Vice-President, A. F. Bronson, of Girardville; Secretary and Treasurer, George Little, of Tamaqua.—The regular meeting of the Syracuse, N. Y., Academy of Medicine was held in that city, January 7.—The Marion County Medical Society held a regular meeting in Indianapolis, Ind., January 7. The following officers were elected for the ensuing year: President, H. M. Lash; Secretary, T. B. Noble; Treasurer, F. B. Wynn.—The Twin City Medical Association held a regular meeting in Kansas City, Mo., January 7.—The Academy of Medicine of Columbus, Ohio, held a regular meeting January 6.—The annual meeting of the Winona County Medical Society was held Winona, Minn., Dec. 31. The following officers were elected: President, W. A. Chamberlain; first Vice-President, D. B. Pritchard; second Vice-President, G. J. Tweedy; Secretary, J. B. McGaughey; Treasurer, E. D. Keyes.—The annual meeting of the Clinton County Medical Society was held in Clinton, Iowa, January 7. The following officers were elected for the ensuing year: President, J. C. Langan; Vice-President, H. G. McCormick; Secretary and Treasurer, P. S. Kaadt.—

The Inter-County Medical Society held its annual meeting in Spring City, Pa., January 2. The following officers were elected for the ensuing year: President, F. W. Heckle, Spring City; Vice-Presidents, William Brower, Spring City; W. Mars teller, Phoenixville; Recording Secretary, J. S. Morey, Royersford; Corresponding Secretary, Dr. Burns, Royersford; Treasurer, Dr. Finkbinder, of Parker Ford.—The Mobile County Medical Society held a regular meeting in Mobile, Ala., January 3. The following officers were installed: President, E. L. Marshal; Vice-President, D. W. Goodman; Secretary, F. R. Sherrard; Treasurer, J. G. Thomas.—At the fifty-first annual meeting of the Northwestern Ohio Medical Association held December 12 and 13, the following officers were elected for the ensuing year: President, Charles Graefe, Sandusky; Vice-Presidents, Dr. Slocum, Defiance, and Dr. Phillips, Belle Center; Secretary, J. B. Baker, Findlay.

Detroit Notes.

THE WAYNE COUNTY MEDICAL SOCIETY at its regular meeting Thursday, January 9, listened to a very interesting paper by Dr. M. V. Meddaugh, entitled "Caloric, Its Utilization in Therapeutics."

THE DETROIT MEDICAL AND LIBRARY ASSOCIATION at its regular meeting Monday, January 6, was entertained by a paper entitled "The Coal Tar Antipyretics," read by Dr. C. J. Jennings.

HEALTH OFFICE REPORT for week ending Jan. 11, 1896: Deaths under 5 years 39, total 92. Births: Male 46, female 43, total 89. Contagious diseases: Diphtheria, last report 23, new cases 28, recovered 14, died 9, now sick 28. Scarlet fever: Last report 20, new cases 6, recovered 8, died none, now sick 18. Smallpox: Last report 2, new cases none, recovered none, died none, now sick 2. Measles: Last report 2, new cases none, recovered none, died none, now sick 2.

St. Louis Notes.

WEEKLY REPORT OF HEALTH OFFICER.—Total number of deaths during the week ending January 11, 189, compared with 180 for the previous week and 146 for the corresponding period of 1895. Contagious diseases reported during the week ending January 11: Diphtheria, 73 cases, 14 deaths; croup, 6 cases, 6 deaths; scarlatina, 7 cases, 1 death; typhoid fever, 3 cases; measles, 9 cases.

THE DUESTROW CASE.—A futile effort has been made to compromise on a life sentence for the insane murderer, and the beginning of the new trial is set for the 13th inst. The prosecution will be satisfied with nothing but a capital punishment, and thus seems bent on prolonging the legal struggle. The case has now become so well known in Franklin County that it will be next to impossible to obtain an unprejudiced jury, and it is now rumored that it will be impossible to convict him there. It is understood that some of the experts for the defense have refused to testify further owing to misunderstandings with the lawyers, but there can be no doubt that the coming trial will again throw discredit on medical testimony.

THE STATE BOARD OF HEALTH met in St. Louis on the 6th inst. and passed the students of the various medical colleges of the State in review on papers submitted by the faculties. It is clear that the board intends to carry out its rules governing the matriculation of students and the recognition of colleges, and it is to be hoped that the board will meet with support from the schools themselves. The present board has done more than any previous one to elevate the standard of medical education, and the classes matriculated this year give clear evidence of the result.

DAIRY INSPECTION. The Health Commissioner is making an effort to have the city government pass an ordinance looking to the thorough inspection of all dairies. At the present time it is impossible to prevent the sale of impure milk, or to cause dairymen to cease to distribute milk from diseased cows. There

have been several discoveries of anthrax and tuberculosis in small herds of late, and yet nothing can be done to prevent the owners from disposing of the milk and the animals. There is an element in the lower house which has heretofore prevented the passage of any ordinance remedying the evil.

Louisville Notes.

U. S. MARINE-HOSPITAL.—Passed Assistant-Surgeon W. P. McIntosh last week relieved Passed Assistant-Surgeon H. T. Goodwin, commanding the U. S. Marine-Hospital here. Dr. Goodwin goes to Stapleton, N. Y., where he was stationed prior to his removal here.

WATER SUPPLY.—In its efforts to secure a pure water supply, the Louisville Water Company has inaugurated a series of competitive tests in order to find the most perfect system of filtration. These tests are carried on four miles east of the city at the pumping station, and so far the city has obtained no benefit from the filtration. Four companies who make a specialty of filtering the water supply of cities have entered the contest, and three of them have their filters at work. The latest claimant for attention is a company which by February 15 will have erected a plant, which it proposes to secure absolute purity of water by means of electricity and magnets. The process was recently described by the agent of the company. The water is run through a standpipe where it receives 200,000 volts of electricity. The pure water under pressure rises to the top and flows off directly into the mains, while the sediment sinks to the bottom and is carried off by another series of pipes. The Water Company requires of each party that enters the contest to erect plants capable of filtering 20,000,000 gallons of water daily, and that these plants shall remain in continuous operation for at least eight months. At the end of this time the filter making the best test will be chosen. In order to facilitate the tests and determine which filter gives the best continuous result, the Water Company has fitted out an extensive laboratory at the pumping station. This is in charge of experts, who make chemic and bacteriologic tests daily.

AMBULANCE SERVICE.—The annual report of the driver of the ambulance shows that for the year ending Jan. 6, 1896, he has answered 1,123 calls.

LONG.—Dr. John L. Long is an applicant for the position of superintendent of the Lakeland Insane Asylum, and has presented some of the very strongest indorsements from the profession and business men of the Fifth Congressional District. The Board of Commissioners and the Louisville Academy of Medicine have indorsed him and urge his appointment by the governor. Dr. Hobbs, of Jefferson County, and Dr. D. T. Smith are also applicants.

ACADEMY OF MEDICINE.—At the last meeting of this society in their rooms in the Louisville College of Pharmacy Building, Dr. Hugh N. Leavell read the essay on chloroform anesthesia. Dr. H. E. Tuley reported a case of scorbutus in a child 12 months old, which had been fed upon dried food from its birth. Dr. I. N. Bloom, in discussing the case, reported a similar one with the same history.

Philadelphia Notes.

AT THE JANUARY MEETING OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA, Dr. J. M. Da Costa was again elected President. Drs. Ernest Leyden of Berlin and Grainger Stewart of Edinburgh were elected to Associate Fellowship. Drs. Patrick Sarsfield Donnellan and Henry Toulmin were elected Fellows of the College. Dr. John B. Roberts presented a specimen of papilloma of the tonsil and Dr. Wm. Hunt some surgical instruments to the Müller Museum. Dr. F. X. Dercum read a communication "On the Functions of the Neuron with Especial Reference to the Phenomena Presented by Hysteria and Hypnotism." Dr. Dercum defined the neuron as the cell-body with all of its processes and claimed for the cell-body special and peculiar physiologic functions in opposition to the view

defended by Dr. Mills that the cell-body has only a trophic function in nerve-centers.

THE PENNSYLVANIA HOSPITAL will erect a new clinical amphitheater and receiving ward during the present year, the plans having been prepared by a committee of the staff and adopted by the managers. The estimated cost is about a hundred thousand dollars.

DR. GEORGE DOCK has been announced as the successor of Dr. Coplin as Professor of Pathology and Bacteriology at Jefferson College. He formerly held a similar position in the University of Texas and more recently in the University of Michigan.

HOUSTON HALL, the new club-house for students of the University of Pennsylvania, was formally opened by Provost Harrison on January 2 and the first smoker was held last Saturday night, when over four hundred students from all the departments were in attendance. The building is a memorial of the son of Mr. H. H. Houston, the young man having died while in attendance at the University some years ago. Mr. Houston gave \$50,000 to the structure and died before it was completed, but his family afterward contributed an equal amount. The building and equipment cost in the neighborhood of \$150,000, the remainder being raised by subscription. It is furnished like a first-class club, including a large swimming pool and a billiard room. There is also a lecture hall with about 360 seats and a miniature stage and dressing rooms, an athletic hall, supper room, and smaller apartment for fraternities, glee and banjo clubs, etc.

DR. WILLIAM T. LUSK, of New York, by invitation of the executive committee of the section on gynecology of the College of Physicians, read a paper on "Recent Bacteriologic Investigations Concerning the Nature of Puerperal Fever," on the 16th inst., at the hall of the College of Physicians. A reception was subsequently given in his honor by the chairman of the section, Dr. Charles B. Penrose at his private residence, which was largely attended by the fellows of the college and other invited guests.

THE PHILADELPHIA CHAPTER of the Alumni Association of the Jefferson Medical College was held January 14, in the college building. Dr. C. Biddle of the Miner's Hospital, Ashland, Pa., by invitation, opened the discussion on the subject of "Sprains." A collation was subsequently held, Dr. S. MacCuen Smith being the host. The annual business meeting of the Alumni Association will be held in the lower lecture room of the college, Saturday, January 18, at 8:30 P.M. Refreshments to be served after the meeting and all graduates of the school are cordially invited to attend.

AT THE ANNUAL MEETING of the Philadelphia County Medical Society held January 15, the following officers were elected for the ensuing year: President, Dr. Jas. C. Wilson, Vice-Presidents, Drs. Jas. Tyson and Thos. J. Mays; Secretary, Dr. I. B. Schneideman; Asst. Secretary, Dr. John Lindsay; Treasurer, Dr. Collier L. Bower.

THIS IS THE WAY the results of the work of the State Board of Medical Examiners and Licensers appear in the public prints: "The three State Medical Boards have sent in reports for the last examinations which they conducted. They are: 'Allopathic' Board, 76 examined, 22 failed; 'Homeopathic' Board, 14 examined, 8 failed; 'Eclectic' Board, 1 examined, none failed."—*Public Ledger*, Jan. 7, 1896.

It would certainly appear that the praiseworthy effort to elevate medical standards has thus far resulted in advancing the cause of sectarian medicine and placing scientific practitioners on a par with homeopaths and eclectics. Who are "allopathic" physicians, anyhow?

Washington Notes.

WEEKLY REPORT OF THE HEALTH DEPARTMENT.—The report of the Health Officer for the week ended January 4 gives the

following summary: Number of deaths (stillbirths not included): White, 52; colored, 26; total, 78. Death rate per 1,000 per annum: White, 14.4; colored, 15.4; total, 14.7. Death rate per 1,000 per annum corresponding week last year: 21.

DEATH OF DR. BAILEY.—The many friends of Dr. Geo. A. Bailey were shocked to learn of his death on the 9th inst., from typhoid fever. Dr. Bailey served as one of the staff of the Citizen's Hospital which flourished during the last Grand Army Encampment here.

ANTHROPOLOGICAL SOCIETY. At the meeting of the Anthropological Society held on the 7th inst., Dr. D. K. Shute, Professor of Anatomy in the Columbia University, read an interesting and instructive paper entitled "Remarks on Racial Anatomical Peculiarities."

THE FORTNIGHTLY CLUB.—The forty-fourth meeting of the club was held on the 10th inst. at the residence of Dr. W. W. Johnston. The evening closed with a most elaborate banquet. A number of invited guests were present. The membership of the club is limited to eighteen M.D.'s.

A NEW CONTAGIOUS HOSPITAL.—There is a current story in effect that the Commissioners will establish shortly at Columbia Heights a pay hospital for contagious diseases.

DECISION IN FAVOR OF THE HOSPITALS. Judge Hagner, in Equity Court No. 2, has decided that under the will of the late Emma L. Breese, the Children's Hospital and Garfield Memorial Hospital are entitled to receive from the estate the sums of \$5,000 and \$50,000 respectively. Mrs. Breese died at Philadelphia July 30, 1892, and the will appointed her sisters, Charlotte Bostwick, of Philadelphia, and Anna Matilda Maulsby, of this city, to be executrices in trust of the estate. This will was dated March 20, 1888, and in a letter addressed to her sisters, Jan. 12, 1891, Mrs. Breese declared that \$5,000 should be given to the Children's Hospital for its endowment fund, interest only to be used, and that \$50,000 should be used for the construction and endowment of a free gynecian hospital for poor and destitute women, to be built on the Garfield Hospital grounds as a branch of that hospital, and to be known as "The Louisa Lovett Fletcher Free Gynecian Hospital." The question to be decided was, "Did the letter constitute a codicil to the will?"

THE WOMEN'S CLINIC. The Women's Clinic has removed to larger quarters to accommodate the increasing work. The new address is 1833 14th Street.

MEDICAL SOCIETY OF THE DISTRICT. At the State meeting of the Society held on the 6th inst., the following officers were unanimously elected: President, Dr. S. C. Busey; Vice-Presidents, Dr. J. W. Boyce and J. H. Bryan; Treasurer, Dr. C. W. Franzoni; Recording Secretary, Dr. S. S. Adams; Corresponding Secretary, Dr. T. C. Smith; Librarian, E. L. Morgan; Board of Examiners, Drs. Kleinschmidt, Acker, Bowen, S. S. Adams and Ober. Censors, Drs. E. F. King, J. T. Winter and Chas. W. Richardson. Dr. Busey enters upon his fourth term as presiding officer, three of which have been consecutive. At the meeting held on the 8th inst., Dr. Ruffin read the essay for the month of January entitled "Treatment of Typhoid Fever." Dr. McArdle reported a case of osteosarcoma of the foot, and presented the specimen. The report of the Committee on the Publication of the Transactions of the Society, was laid over for discussion at the next regular meeting.

THE POST GRADUATE SCHOOL OF MEDICINE OF THE DISTRICT OF COLUMBIA. The bill to incorporate the Post Graduate School of Medicine was favorably reported by Senator Gallenger, on the 10th inst., and upon his motion was unanimously passed by the Senate. Senator Gallenger is a homeopath physician and all medical matters arising in the Senate are referred to him for a medico-senatorial opinion. The Senator is greatly interested in medical advancement and gives all such matters his personal attention.

REQUEST OF THE DENTISTS. The dentists of this city have united in asking for an amendment to the medical practice bill, now pending before Congress, which is broad in scope. It reads as follows: "Provided that nothing in this act shall limit dentists who are duly registered in compliance with the law applying to that branch of the healing art, in the practice

of medicine and surgery with relation to the teeth, mouth, jaws, and associated parts." The adoption of the amendment would seem to give dentists full right to practice medicine as regular physicians.

THE PUBLIC SERVICE.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from January 4, 1896, to January 10, 1896.

The appointment of James Sprigg Wilson to be Assistant Surgeon with the rank of First Lieutenant, to date from Dec. 16, 1895, is announced. He will report in person without delay to the president of the Army Medical School for instruction. Major Clarence Ewen, Surgeon, is granted leave of absence for six months, on account of disability.

Change of Address.

Bowle, M. K., from Barber Bldg to Saus Bldg, Joliet, Ill.
Connell, M. E., from Wauwatosa, Wis., to 710 Jackson Boul., Chicago, Ill.
Davis, H. L., from 14 Fowley Street to 2962 Wabash Avenue, Chicago, Ill.
Herman, M., from Washington, D. C., to 1535 Callopie Street, New Orleans, La.
Loar, L. T., from Dingess, W. Va., to Darbyville, Ohio.
Mennett, O. H., street address cor. Vermont Avenue and Jefferson Street, Los Angeles, Cal.
Neyman, E. H., from cor. Reed Street and National Avenue to 30 and 31 Mack Block (cor. East Water and Wisconsin Streets), Milwaukee, Wis.
Prentiss, D. W., from Washington, D. C., to Harrington House, Hamilton Parish, Bermuda.
Potts, J. S., from San Jose to 206 S. Broadway, Los Angeles, Cal.
Russell, L. B., from Goodwin to Hoopston, Ill.
Rives, W. C., from Washington, D. C., to 22 W. 33d Street, New York, N. Y.
Schmidt, O. L., from 103 Randolph Street to 3328 Michigan Avenue, Chicago, Ill.
The Medical News, from Philadelphia, Pa., to 111 Fifth Avenue (cor. 18th Street), New York, N. Y.
Thomas, John D., from 1400 K Street N. W. to The Cairo, Washington, D. C.

No. 4.

ADDRESS.

CHAIRMAN'S ADDRESS.

Delivered in the Section on Dental and Oral Surgery, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY M. H. FLETCHER, M.D., D.D.S.

CINCINNATI, OHIO.

I acknowledge with pleasure the courtesy shown me, in again selecting me as presiding officer; though this Section is not large as a national body, the quality of its work is second to none, and its influences are unbounded. Its tendency is to elevate to a higher standard thereby advancing the science of the profession. In looking back over the past twelve months, these marks of progress are encouragingly conspicuous and, we believe, point to a steady and healthy growth. This is indicated by the increased number of practical scientific workers who are coming forward; by books of scientific value second to none in their line; by numbers of good papers and discussions on important topics, many of which have served largely to add to our fund of knowledge. Errors have been eliminated which is equally important with new discoveries. Superstition and guessing are giving place to accuracy and precision.

It is a fact that all the professions which have man himself for their subject, which aim to rectify his physical deficiencies, are to-day, and always have been, of the greatest interest; their scientific advancements in the past decade are more marked than in any previous one, but our lack of knowledge is still very great. Through the kindness of nature in maintaining her laws regardless of all theories and methods, our patients recover and are even grateful, believing the result to be in exact accord with the laws which we are supposed to understand; but though we may have been both honest and conscientious in our work, does this lessen our responsibility? In other words should we not, and can we not, know better than we do? And do we take all means accessible to inform ourselves?

When we work or reason from wrong principles, nature keeps coming back at us with the same conditions and by continuous knocking at our obtuseness, tries to show us the right way; and when at last we perceive and accept her teachings, we become through our enlightenment, the true benefactors of mankind, and I take it that there is no nobler nor happier position in which a man may find himself. Now in order that we may attain this desirable position, our minds must be constantly on the alert, willing to correct errors, and sensitive to new truths, much as the photographer's plate is sensitive to light and shadow. This might seem a dry and monotonous pass-time, but those who have tried it longest, have gained the most pleasure from life, and have been of greatest usefulness. Lubbock says, "Those who have not tried for

themselves, can hardly imagine how much science adds to the interest and variety of life." This kind of life and work gives us all the poetry we may desire with a limitless field for imagination; it gives us art, for nature is art; it gives us history, for facts about people and nations is history; it gives us science, for knowledge of the laws of the universe is science. Nor is this the limit, for after all our seeking there yet remain truths that are beyond the mind of man to conceive.

I am aware that when I touch upon the best methods of educating students for our profession, I run the risk of being prosy and tiresome; but the subject bears so directly on our standing in the future, that I presume upon your courtesy to the chair, and take advantage of my opportunity. Discussion of this point has not been confined to our specialty alone. Educators in almost every line have been much agitated over the same problem. I am persuaded from what I have read and observed on this topic, that a good way to try to solve the question is through the study of mental philosophy, the laws of which within certain limits are as unchangeable as those pertaining to the physical man. Now if we take into consideration, the fact that it is through sense perception that we receive all our knowledge, would it not seem that the technique classes or laboratory methods would be the most natural channel through which to educate not only our students, but those in all branches of medicine. Recall for instance the delicate technique required of the successful surgeon, the oculist, the throat specialist or gynecologist; even the general practitioner needs a gentle and educated touch, and a most thoroughly trained mind in reasoning from cause to effect, and effect to cause. Good and accurate results come only to him who has learned how to reason after this manner, first on the simplest matters in philosophy; then gradually going on step by step, until he is able to handle in a practical way the more obtruse problems. This training begins in babyhood, from the time the infant first notices the candle light, and by experiment learns that if he touches it, he suffers pain. Thus he accumulates one fact after another, until he finally reaches the last stages of mental development, that of judgment and ideation. In connection with this subject of mental ripening, comes the question, which has been somewhat discussed, as to whether a student showing no adaptability in learning the branches he has chosen, should be allowed to continue at such work; or whether he should be shown his defects, and encouraged to try some branch of work for which he may have capabilities. Pertinent to this point, there is in the February number of *The Educational Review*, an article on "The Education of the Nervous System" by Henry H. Donaldson, in which he says, "No amount of education will cause enlargement or organization where the rough materials, the cells are

wanting; and on the other hand where these materials are present, they will in some degree become evident, whether purposely educated or not;" he further says, "on neurologic grounds, therefore, nurture is to be considered of much less importance than nature, and in that sense the capacities that we most admire in persons worthy of remark, are certainly born rather than made."

Again he says, in speaking of early mental ripening or precocity, "The same conditions which give the individual a generously planned nervous system also favor its early development." In such precocious persons it tends to grow for a longer period than usual, a feature which is fully as important as the precocity itself. It is extremely interesting to see how, among a series of eminent men, excluding men of action, the determination of distinction follows the order in which the brain normally attains the high development necessary to command recognition in a particular profession. He gives the following table based on 287 cases analyzed by Prof. James Sully.

287 Cases analyzed by Professor Sully.	Gave Promise Before 20 Years Old.	Produced Before 30 Years Old.	Attained Distinction Before 40 Years Old.
Musicians	95 per cent.	100 per cent.	100 per cent.
Artists	89 per cent.	98 per cent.	100 per cent.
Scholars	83 per cent.	71 per cent.	90 per cent.
Poets	75 per cent.	92 per cent.	92 per cent.
Scientists	75 per cent.	80 per cent.	92 per cent.
Novelists	75 per cent.	56 per cent.	80 per cent.
Philosophers . . .	67 per cent.	56 per cent.	60 per cent.

"Those professions demanding only small acquisition but a very perfect adjustment between one sense organ and one set of muscles, as between the hand and the ear in the musician, and the eye and the hand in the artist, are precocious throughout, while the philosophers with their need for accumulated information and ripened judgment bring up the rear. Similar investigations on slightly different material yield accordant results."

The art of our profession would naturally compare with the artist in the table, for success in this department is dependent upon the training and skill of the eye and the hand; again, the science of the profession compares with the scientists in the table, who come much lower in the list, showing the necessity for more strength of mind, and a greater accumulation of facts. But to be simply an artisan and a scientist, is not sufficient to enable one to reach the highest standard of usefulness as a practitioner of medicine or its specialties. In our own division one needs to be somewhat proficient in at least four callings, namely: As an artist, a scholar, a scientist and a philosopher. If one of fair ability honestly endeavors to meet the demands of his profession in these four callings, all things desirable will be at his command.

It must be evident that it matters not whether a student be dull or precocious, the amount of his knowledge is proportional to his accumulation of facts and his ability to recall and utilize them. Different men have different abilities. Some persons do with great ease or almost intuitively those things that are only done with the greatest effort by others if they succeed at all. This being the case, the standard of license to practice any department of medicine should be so guarded that no incompetent person could enter its ranks. As to the best methods of educating for this standard, the most natural, as before stated, is that method in which the senses convey knowledge by contact with the objects and

phenomena in actual work, at first in its simplest form, then gradually leading step by step to perfection; by this method the mind is stored with facts and trained to reason, and use them to the end desired.

The "technic system" of teaching was very ably presented last May by Dr. Edward C. Kirk, before the Academy of Dental Science of Boston and well discussed by its members; and I wish to say that I heartily agree with the essayist. There is, however, one feature of education in both dental and medical colleges, which was only touched upon in the paper and mentioned by no one during its discussion, yet I consider it a question of the greatest importance. It is that of having suitably trained instructors in our colleges. This I deem to be as great a defect as any at the present time in our system of teaching.

At the last meeting of the American Dental Association during the discussion of the report of the committee on dental education, Dr. H. J. McKellops struck the key note when he said, "Give me the man who can teach science." If a student is bright and apt in his college work he will make good progress under almost any circumstances, but if he makes good progress with poor instruction, how much better would he do under thoroughly trained teachers. It has been my pleasure to be a student, under instruction, in some branch almost continuously for the past eighteen years, and this feature of ability, or lack of it, to impart knowledge is a point that has impressed me very strongly, with every change of subject and instructor. It is not every one that has knowledge who knows how to impart it intelligently, and the fewer number know how to present a subject in a form most suited to the mental status of their hearers. If the capabilities of all students were equal, and their interest in progress were the same, the matter would not present so many difficulties to the instructor, but were these conditions possible, the same class would progress much more rapidly under one teacher than under another. An article in a recent magazine by a college student compares two professors in the following manner: "Though he thoroughly knows his subject, his instruction is about as clear as mud; with him everything is 'perfectly obvious,' but to us his attempts at exposition are positively confusing; he thinks only of his subject, never of his students; he is cold, unsympathetic, unapproachable. I want to know the nature of this requirement for to-morrow, but if I ask him he will either show impatience at my ignorance or temerity, or misconstrue the motive of my inquiry and stand upon his pedestal of superior knowledge. But with Professor X. we make headway; he seems anxious and able to make every thing clear; he puts himself in his pupil's place; he is always willing to remain after the lecture to answer questions or discuss debatable points."

Charles C. Ramsay, in the January number of the *Educational Review*, speaks of this subject as follows: "True teaching, whether in school or college, is the process of causing another to know through self-activity, and includes the mutual effort of two persons to the same end, the teacher and the learner. Until the two are at this common work the process of teaching has not been begun; until the learner has learned the teacher has not taught." And let it be remembered that the proof of the teaching process always rests with the learner, not with the teacher, whether the scholars be young or old. "The teacher

can prove that he tried to teach; the scholar alone can show that the teacher succeeded." "The measure of information," said Pestalozzi, "is not what the teacher can give, but what the pupil can receive." These fundamental principles of all good teaching are as applicable to collegiate as to elementary and secondary instruction.

Now, if this be the case in literary institutions and universities, where the professors and teachers give their entire time to this work, and should know how to do it in the best possible manner, how much more is it true in dental and medical colleges, where the teaching is done by men whose time is almost wholly taken up with a busy practice; many of them are eminent and skilled in their professional duties, yet are quite marked for their lack of ability to teach; nevertheless, their students are expected to reach a high standard under their tutorage. Is it any wonder then that students pony, and resort to all kinds of methods for getting assistance at examinations, under such conditions?

The subject as to whether the lecture method or that of recitation is best, has been pretty fully discussed amongst our educators, but whichever method is adopted it in no way makes a good or bad teacher. Now, if one needs so much training in order to properly fill a simple cavity or extract a tooth, a procedure which seems so simple to us, how much greater his obligation to be properly prepared before attempting to direct and instruct the intellect of others. The loss of teeth or a limb may be replaced by artificial substitutes, but the loss of time can never be replaced; and time to many students is as valuable as to the professor; probably not from an immediate financial standpoint, but the loss of time to an earnest, intelligent student at an age when he is studying a profession is not a trivial matter. You may say that many students or even most of them care but little for their time, or what they learn, so they are graduated and given a license to practice; granting this to be true, it is all the greater reflection upon their instructors for if the work was made more interesting the number of attentive students would increase proportionally and develop into the kind of practitioner we delight to recognize; it is a known fact that it is not always the pupils who stand highest in a class that show the best results in after life; the plodding, honest ones in almost every class many times outnumber the precocious ones; and under the guidance of properly trained and intelligent instructors, the number of honest plodders might be increased from the ranks of those who are apparently dull and careless, and the list of precocious might be enlarged from those who are brilliant and capable, but who fritter away their time in gait and foolishness. It is not an uncommon thing to find in a class students who outrank many of their professors in strength of intellect and natural ability; not only these, but all students have a right to demand that their instruction be presented to them in the best possible manner.

It is a perfectly easy matter to get professors for the asking, but trained instructors are rare; and even those who have the natural qualities to become good instructors are not numerous. No one doubts that we have professors in almost every college who are thoroughly capable, and who take time and pains to be what they should to the student, but on the other and, a greater number fall far short of this standard.

I believe a majority of students in all colleges are

industrious, and of good intent, and many of them are barely able financially to carry through a three or four years' course; such students, if denied the full measure of their capacities to receive, are defrauded of both money and time, the first of which never is, and the last never can be repaid. There are no normal schools, so far as I know, for the proper training of dental and medical teachers, and if there were, it does not seem practicable for many of our eminent practitioners, who are in other respects most suited for the position of instructors, to leave work and go to other localities for such training; but such a normal school, it seems to me, is demanded in some suitable form, and it would seem a most fitting topic for discussion and action by our national associations of faculties. The distance a missile flies and the velocity with which it goes, is exactly proportional to the force which impels it. The analogy holds good in our colleges, for students of high grade can not be graduated unless the force can be found in their Alma Mater to produce the desired result; consequently, it would seem no more necessary, if as much, to lengthen the term at college, increase the curriculum, and raise the standard of entrance, than it is to increase the quality and ability of college instructors.

ORIGINAL ARTICLES.

ELECTRICITY.

Read in the Section on Physiology and Dietetics, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY E. H. WOOLSEY, M.D.

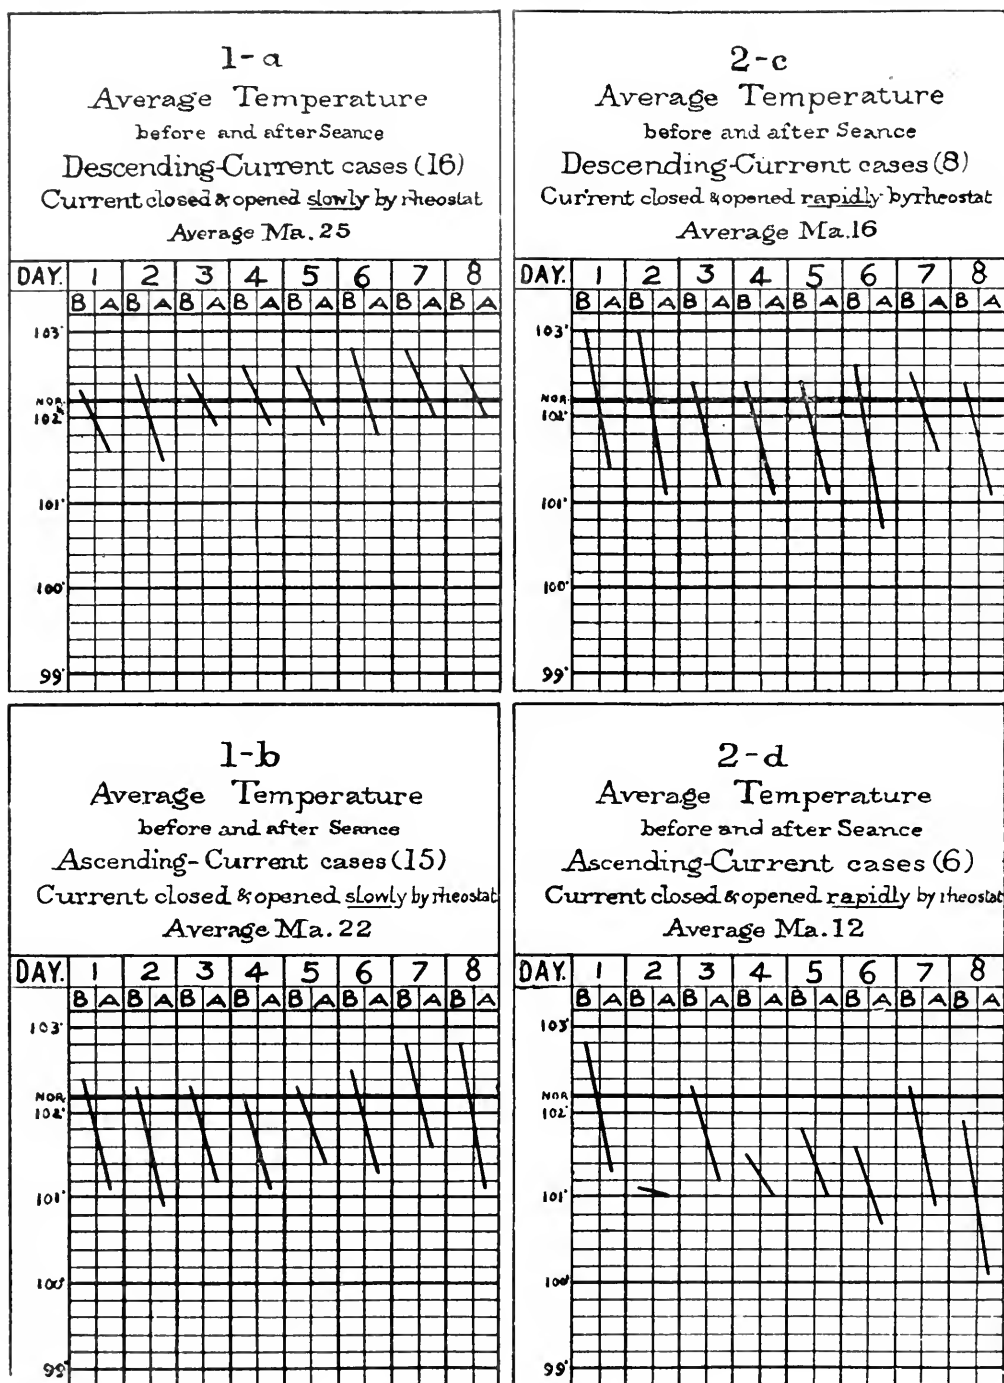

CHAIRMAN OF SECTION.
OAKLAND, CAL.

Last year I presented to this section a tabulated statement of observations made upon rabbits treated by electricity. This experimental work has been continued along nearly the same lines as heretofore, and some additional effects of electricity not previously anticipated have been noted. The observations on the last series of sixteen cases treated, however, have not been tabulated, for I intend to pursue this work further and ultimately to arrange a complete summary of all observations.

In addition to what I have previously said as to polar influence on the spinal cord, lungs, bladder, etc., I have now to announce that with the electrodes placed as I have always used them in the so-called descending and ascending current cases, all of the abdominal viscera are usually affected differently by a different direction of current. The strength of the current used in the last series of experiments varied in different cases from 5 to 20 ma., and in different sets of cases was delivered differently, and yet it was almost uniformly found that the kidneys were congested and the mucous coat of the stomach moist and the contents of the stomach moist in the descending-current cases, and that exactly reversed conditions obtained in the ascending-current cases.

The only line of observations I have worked out to a finish is that on the influence of electricity upon temperature, and I herewith present a series of temperature charts with explanations.

I may here remark that, notwithstanding all statements to the contrary, the immediate effect of galvanism, however administered, is to lower the vital temperature, that this is followed by a reaction which reaches somewhat higher than normal, and this by a

GRAPHIC CHARTS.

Illustrating the Influence of Galvanism on Vital Temperature. Experimentation on Adult Domestic Rabbits.

Readings of charts 1-a to 7 inclusive show temperature observations before and after seance daily for a period of eight days, and of chart 8 at the several times indicated during a period of eight hours following seance.

Seance ten minutes. Milliamperage always the same in each case, but in different cases varied from 5 to 80. Temperature taken carefully by Hicks' thermometer in rectum.

(Normal temperature of rabbits 102.2°, previously determined by taking average of first observations, in the first thirty-one healthy rabbits experimented upon.)

Used stationary gravity battery, Weston's milliamperemeter, Massey's current controller, copper electrodes, $\frac{3}{4} \times 1\frac{1}{4}$ inch, covered by lint wet in salt solution and fixed by body straps over shaved skin at cervico-dorsal and lower lumbar regions of spine.

second reaction which reaches yet higher, and which is succeeded by a fall to near the normal; moreover, that after several days' treatment with strong currents, however delivered, there is a feverish reaction. In general terms it may be said that the stronger the current and the greater the shock in its delivery, the greater will be the fall and the more pronounced the reaction.

I will present to you a few cases which I have selected from my records which will show the range of usefulness of galvanism and incidentally illustrate my methods.

Case 1. Locomotor Ataxia. J. H., 42; locomotive engineer; admitted to my private hospital in 1884 with locomotor ataxia; could scarcely walk with eyes open and could neither stand nor sit steadily with eyes closed; no response of reflexes; perfect anesthesia below the knees; mind occupied constantly with

delusions, recognizing members of his family as embodiments of stranger spirits. At end of three months' treatment, consisting chiefly of galvanism, he had some knee-jerk and some sensation of legs and feet and his mind, though occupied by some harmless spiritual delusions, was practically restored to usefulness, and he was discharged for duty, but not to resume his former occupation. He, however, was considered well enough to return to his engine and did so, working for six months, when one day impelled by a spirit to run down a tramp on a trestle, killed him.

He was re-admitted to hospital in about the same condition as upon first admission, though his mind was even more perturbed. He was treated again in the same way as before for two months, and was again discharged as able to work and as fully recovered as at time of previous discharge. Since then he has worked steadily as a machinist. I saw him a few weeks ago and he has again lost the knee-jerk: has lately suffered from numbness of the feet: his mind is slightly perturbed, and he has become somewhat deaf, but is still able to do good work.

In this case I used a mild, stabile, galvanic current: one electrode at feet, the other—three inches wide by one foot long

—over upper part of spine: seance ten minutes daily: direction of current chiefly upward, though reversed to downward direction once or twice during seance, yet always finishing with the ascending current.

Remarks.—This is my usual treatment in cases of this class, modified more or less as to the number of reversals; frequently reversing about every two minutes, but finishing usually with the ascending current; also occasionally modified by labile treatment of the spine and incidentally to other parts of the back, pausing for an instant, especially when handling the positive electrode, at tender or painful points. Occasionally the forgoing practice is modified by placing the upper electrode in the patient's hands. This I believe to be good practice, for in such cases the functions of the upper extremities as well as of the lower are frequently at fault, and

Number of observations on temperature.— before and after Seance, in descending and ascending-current cases. [some of above cases treated longer than eight days] 483

No instances of rise of temp. 41 or 8.49 prct
 " fall " 415 or 85.92 " "
 " " same " 27 or 5.59 " "

stable electricity at hands and feet meet special indications here, besides conditioning such extensive diffusion of the current through the body as to meet most other indications, though the direct application over the spine and particularly over affected areas may be of great utility. In the matter of reversal of current, it is in most cases better to remove one of the electrodes before using the pole-changer for the shock will be very much less; and for the same reason it is even better to gradually withdraw the current by a rheostat before reversing, and then after the change, to slowly turn the current on again.

In regard to current strength my experience is in accord with the growing tendency of electricians to use weaker currents. The terms mild or weak, medium and strong, are only relative, and significant only of the individual views of different writers, one

for example, considering 15 to 20 ma. as mild and 100 ma. as not over strong; another, 10 ma., 20 ma. and 50 ma. as respectively mild, medium and strong; while others with whom I concur, consider that the range of therapeutic currents should be placed very much lower. In spinal cases I commonly use a current of from 5 to 10 ma., though in some cases as low as 3 ma. and in others as high as 30 ma. No definite rule as to strength of current can be laid down for the treatment of this class of cases. However, it may be said in a general way and fairly applicable to all classes of cases, that the current which will usually be most useful is that which the patient can just barely feel. By this rule, however, the milliamperage will vary considerably in different cases on account of individual peculiarities due to the influence of idiosyncrasy or disease. More voltage will

be required if the circuit resistance is increased; if, for example, the patient's skin is dry, or the sponge or other covering of electrodes is imperfectly moistened, or the conducting wires or terminals are rusty; yet, with all such impediments, provided a current of desired strength can be steadily maintained, the treatment may be perfect. Of late there has been much discussion as to the quality of surface electrodes, and I consider that the medical electrician should aim to secure as perfect conductivity as possible; practically that he should not lose sight of the fact that clean metallic connections and perfect moisture of electrodes are useful, and that the conductivity of water is increased by warmth and also by the addition of salt; but it must nevertheless appear that even poor conductivity may exist, and yet, as long as it permits of a steady flow of current, and the voltage can be depended upon to yield a current of sufficient strength to meet the requirements of a case, that there may be no fault of treatment. Whatever resistance may be encountered a perfect milliamperemeter will show the current delivered, and I may here add that a perfect milliamperemeter is indispensable.

Ten minutes has been given as the usual length of séance. It is necessary to consider the quantity of electricity administered, and until we have a more practical means of measuring coulombs we must consider time as an essential factor, and it is therefore necessary to fix arbitrarily a limit to the length of séance. This question is occupying much attention at the present time, and the tendency now is to diminish the dosage of electricity, not only by giving a weaker current, but by shortening the séance.

Experimentation on rabbits has convinced me that the length of séance has a most material influence, for I have observed under uniform conditions that the effect of electricity upon nutrition of internal organs is more pronounced when a current of 10 ma. is given fifteen minutes than when it is given ten minutes; and that a current of 5 ma. given fifteen minutes will produce effects similar to the effects of a current of 15 ma. given five minutes.

At the beginning of treatment daily séances are usually in order that obtained effects shall be maintained, and even two short séances a day may in some cases be useful; but generally speaking, after a patient has begun to show marked signs of improvement, which usually appear when the current is well adapted—in from one to two weeks—then the course of treatment should be broken by giving only four or five séances a week; and as the case progresses the treatment should be less and less frequent; and it may here be remarked, that for similar reasons it is also necessary, when a patient begins to show marked signs of improvement, to diminish either the strength of current or the length of séance or both. My reason for these remarks on interruption of treatment, etc., is that patients, and animals as well, usually show under the influence of daily treatment an increasing susceptibility to electricity, and in the course of a week or two usually exhibit some irritability of temper and, as before stated, especially when giving strong currents, a reactionary rise of temperature; and also exhibit other evidences of being overcharged or over-treated—evidences that electricity is cumulative, or that its effects are so.

One of the first signs of improvement in cases of chronic disease of the spinal cord treated by elec-

tricity is the rise of the patient's temperature. It may not be generally known that the temperature of such patients is almost invariably subnormal and frequently very low; but this is nevertheless a fact which I have determined by a long experience, and a fact which I have come to regard as of great diagnostic value.

This curative rise of subnormal temperature should not be confounded with the reactionary rise of temperature occurring in other classes of cases, and referred to as a result of protracted treatment; nor is there any conflict here with the fact, illustrated by the temperature charts, that the immediate effect of electricity is to cause a temporary fall of temperature.

In an analysis of the tabulated effects of electricity upon rabbits presented to this Section last year I drew the conclusion that "in a downward current the ultimate anodal influence is to cause anemia, and in an upward current the ultimate cathodal influence is to cause hyperemia;" and I am still impressed with this view.

From my earliest successful use of the constant current, I have entertained the opinion that current direction and polar influence were the most important factors connected with its administration. The presumed effect upon the blood vessels by the influence of the positive pole upon the vaso-constrictors and of the negative pole upon the vaso-dilators always seemed to me an easy explanation of the phenomena observed in practice; and my further experience and experimentation strengthen this view.

The catalytic action of electricity no doubt plays an important rôle here, and I am prone to believe that the *modus operandi* of such action most necessary to nutrition is, as Goelet has pointed out, the influence of electricity upon oxygen within the body in changing it into ozone. Erb says that catalytic action is independent of direction of current and yet, while considering chronic forms of disease of the spinal cord he says, "this action alone explains the rationale of cure of such diseases."

REPORT OF CASES CONTINUED.

Case 2. Tetanus. In 1884, M. L., 40; butcher; admitted to hospital with tetanus, caused by a superficial scalp wound which was foul, but readily healed under antiseptic treatment. The opisthotonos was extreme, the trismus was complete, and his efforts at inspiration were distressing and accompanied by a shriek. The battery I used then was a stationary, gravity, 50-cell battery; but at that time the current was delivered by a switch without the use of rheostat or milliamperemeter. I applied a stable descending-current, the anode at the entire spine, supported by a pillow as his body was arched forward, and the cathode at the feet, and turned on the full force of the battery, the latter being in an active condition. This current was maintained for six hours without sensible improvement: was then suspended for an hour, and then reapplied and continued for the night, and on the following morning the patient was better respiration less shallow, expiration less noisy. There was less trismus but mouth could not be opened. The current was withdrawn, but after an hour the convulsions were violent. The current was again applied as before and in less than an hour the symptoms abated slightly, and the current was again withdrawn. In a few minutes severe spasm and rigid opisthotonos again returned, but the application of the current caused some apparent relief in the course of a half hour. It now became evident that we had the case under some control, and the electrodes were left in place (except as they were removed for purpose of moistening); and when the symptoms were aggravated the current was turned on, and when they abated it was turned off: as yet, however, the patient could not move a muscle of his body.

On the third day, when under the influence of the current, his mouth could be forcibly opened a little, and for the first time he swallowed a little water—teaspoonful at a time—but did this with great difficulty: but even now when the current

was withdrawn for an hour or so, spasms returned and instantly held him so rigidly that no external muscle could have been forcibly relaxed without rupture. (About this time an attempt of a new heroic nurse to bend him resulted in the breaking of the foot of the bedstead.) Gradually the current acted more promptly and had a more relaxing effect and the recurrence of spasms became less frequent. In the course of a week the spasms yielded within a minute after turning on the current, and during intervals of repose patient was fairly comfortable and could take liquid nourishment, but he was too sore to move, as the muscles, abdominal and thoracic, as well as those of extremities, seemed to have been nearly torn from their attachments by the violence and persistence of the spasms.

About this time, on an occasion of recurrence of spasms I administered the current experimentally in an upward direction, but instead of controlling the spasm it increased its severity, and upon reversing the current to a downward direction the spasm was again abated. From this time on the current was gradually reduced and the time of its administration diminished. At the end of three weeks' treatment the patient was discharged recovered, though his muscles were yet so sore and stiff from previous tension that upon rising from his bed or chair he could scarcely move for some minutes, and he could not turn his head, but the stiffness gradually disappeared, and he is still alive and well.

Remarks.—In this connection it may be of some interest to state that when a current of extraordinary strength, 70 to 100 ma., is delivered to a rabbit in the descending direction, the spine will be arched forward and the head and tail drawn up; and when delivered in the ascending direction, the spine will be arched backward and the head drawn somewhat downward and close to the trunk, and the tail drawn downward and forward; and moreover, that such contortions will follow such current direction however frequently the current is reversed; and moreover, that rabbits thus severely shocked by such reversals of such current, are likely to die in the course of a few hours with convulsions of a tetanic character.

Case 3. Locomotor Ataxia, from Diphtheria. In 1886, I treated the six-year-old son of S. G. for locomotor ataxia, resulting from a protracted, severe attack of diphtheria. He could not walk even with his eyes open without falling, and had returned to creeping. The reflexes at soles and knees were entirely abolished, and he had aphonia. I called in consultation the ablest neurologist on the Pacific Coast, who agreed with me as to the probable utility of electricity, but he advised the faradic current to be applied to the neck and the galvanic current to the spine, and expressed the opinion that direction of the current was immaterial. The patient's temperature was 96.5. I commenced the treatment as suggested, giving daily seances applied the faradic current to the neck, about as strong as the patient could bear for five minutes, and with electrodes at the feet and spine gave a stabile, downward, galvanic current of 10 ma., delivered by switch, for ten minutes. This treatment was continued for a week, when patient had not only not improved but was rather worse in every respect. I then discontinued the faradic current and applied the galvanic current in an upward direction, but in other respects precisely as before—same strength of current, same time, etc. At the end of the second week there was some improvement; the voice had increased from a low to a husky whisper, and patient could stand a little longer on his feet; his temperature has risen to 97.3—nearly a degree, but there was not the slightest response of reflex tendons. This treatment, namely, the ascending current was continued, though the strength of current was lowered to 6 ma., and the length of seance reduced to eight minutes. At the end of the fourth week the patient was nearly well, though the knee-jerk was still only just perceptible. The temperature had become normal; the voice had returned, though was yet somewhat weak; and he could walk about for a half hour without assistance. Treatment was continued, though only three times a week, for another month, when patient had fully recovered in every respect. He is now alive and well.

Case 4. Locomotor Ataxia, from Tobacco. In 1886, J. F., 38; laborer; admitted to hospital on account of locomotor ataxia. He could not stand or even sit erect with his eyes closed, and staggered like one intoxicated when walking with eyes open. Patellar reflexes absent and no response at soles; skin generally more or less anesthetic did not feel ordinary

pin pricking even at arms or neck or face, nor deep pin pricking at lower extremities; mind not impaired, but speech sluggish. Cause of ataxia seemed to be from excessive use of tobacco. Gave stabile current of 20 ma., delivered by switch to foot and spine electrodes, ten minutes daily; and for three consecutive days, experimentally in a descending direction, with the effect of aggravating the symptoms. Then I administered the same current in an ascending direction and the patient at once—during and immediately after the seance, expressed himself as feeling better and his voice was stronger and he looked brighter. This treatment was persisted in daily except Sundays, and there was daily improvement; sensation and activity of reflexes gradually returned and the ataxia gradually disappeared and he was discharged fully recovered at the end of three weeks' treatment, and has since remained well.

Case 5.—Spinal Meningitis, from Concussion. In 1886, J. L. P., 30, brakeman, admitted to hospital on account of concussion of spine from railway collision. After five weeks' general treatment the acute distressing symptoms passed off but left an apparent congestion at the upper dorsal spine where, upon pressure, there was tenderness and pain, and after exercise severe intercostal pains. A current of 3 to 10 ma. was applied—positive electrode moved over tender part of spine and negative electrode fixed at buttocks. During the seance of ten minutes, finding that he could not at once stand 10 ma., a weak current was given, and after a minute or so he could tolerate it a little stronger, and before the close of the seance could stand 10 ma., providing the electrode over the spine was kept in motion. This treatment was repeated daily for six days when the sensitiveness on pressure and the exaggerated electro-sensibility had greatly diminished. Then, however, the house physician gave the current accidentally in an upward direction with the effect of waking up morbid sensibility of the spine and rendering the patient more nervous and irritable, and that night he was unusually restless. On the following day the regular treatment, descending current, was used, causing immediate relief of tenderness and nervousness and the patient slept for an hour immediately after the seance. This treatment was continued daily except Sundays for two weeks longer, when the patient was discharged. He worked as ticket collector for three years without interruption though suffering at times for a few hours, and occasionally at night, from pain at upper part of back. He was assigned to duty as brakeman and after a few days of such work was again admitted to hospital, in 1890, with acute, spinal meningitis. The dyspnea on account of intercostal neuralgia, etc., was distressing, and cyanosis was marked, and he complained of pain at the back, neck and head, and also at the extremities. He was kept constantly under the influence of morphia. His wife and brother-in-law—a physician, and the membership of the hospital staff expected his death daily. This was the condition in which I found him four weeks after his admission. At once I applied a stabile, downward current without disturbing him much in bed, anode about one foot long and three inches wide over the most sensitive part of the spine, the upper dorsal and lower cervical, and cathode at feet. I began with 5 ma. and increased to 12 ma. during a seance of ten minutes and the relief was almost instantaneous; and before the seance was over patient went to sleep. This treatment was given twice daily for several days and each time with the effect of causing sleep before the seance ended. The patient gradually improved and the number of seances was diminished, but the rather strong current was kept up as the patient always asked to have it stronger, and on some occasions, through the offices of an indiscreet fellow-patient, he got as high as 40 ma. and yet with apparent good effect. But after about two weeks' treatment patient began to complain of pain in the left leg and of abnormal sensations at the foot and of a drawing feeling at the toes. He had now so far recovered that all anodynes had been withdrawn: he was able to sit up in bed; soreness and pain at back and neck had largely abated and his appetite had returned. I continued the treatment daily, except using a weaker current 8 to 10 ma., for a month longer, always with agreeable immediate effects and the spinal tenderness had entirely disappeared; and there was but one complaint, that of pains at left leg and foot. He could walk about town and felt himself improving from day to day, but his face began to be a little edematous. The treatment was continued and there was no indication of return of spinal irritation; but each day there was some new phase of edema and soon it became quite general and very pronounced, the skin being distended to its utmost, and though patient could yet walk when raised up, he could not rise from his bed unassisted. The heart and urine were examined but no evidence of organic lesion was discovered. I now suspected that the current had caused it, and putting my theory to a

further test, gave an ascending current of the same strength—stable, with anode at feet and cathode at lower part of back, keeping far below the site of original irritation. On some days of treatment a transitory irritating effect was occasioned at the meninges of the upper dorsal portion of the cord, but this was always promptly controlled by the temporary application here of the positive pole. After the first day's treatment with the ascending current, the edema began to subside, and during a ten days' course of such treatment entirely disappeared and with it the numbness of left leg; and the patient was discharged recovered. He went to work as flagman and continued at such work for several months, but then caught cold and died suddenly of pneumonia.

Case 6.—Cerebral Hyperemia, from Loss of Sleep. In 1888, Lieutenant L., 28, was admitted to hospital in consequence of having been on ship duty for five consecutive days and nights. He had paroxysms of cerebral hyperemia coming on suddenly several times a day, though there was some premonition such as vertigo and headache. When having such symptoms he could walk a short distance—a half block or so, with staggering gait, but then had to lie down or fall. Upon lying down or falling he would flex his body strongly, and become unconscious and the torpor would be so deep that he could not be waked; but in an hour or so would wake voluntarily and remember what had occurred up to the moment of such sleep. When these spells came on the face became flushed and during the period of unconsciousness cyanosed, but upon waking would resume its natural pale color. Under medication it was found that nothing would abort the paroxysms, but that a large dose of bromid of potassium or soda given promptly when the face began to flush, would render the paroxysm less severe, though the after effect seemed to be injurious, as it left him in a semi-torpid condition for some time after the ordinary duration of the spell. After several days' treatment, he happened one day, when a paroxysm was coming on, to be in the office where galvanism was accessible and I quickly applied a current of 5 ma. to head, moving the positive pole over the forehead and holding the negative pole steadily at back of neck and continued this treatment for five minutes. He experienced immediate relief: the flushing and headache disappeared and the paroxysm was averted. From this time on the same electrical treatment was given whenever he had any flushing of face or headache, and always with the same salutary effect. In the course of a few days, however, it was found that a seance of a minute was all that was required. After two weeks of such treatment the patient seemed perfectly well, but the momentary application of the current was made occasionally, when the patient felt the least anxiety about himself, for some two weeks longer, when he was discharged convalescent, but was advised not to do any mental work for a long period. He, however, soon after resumed his studies: visited Washington and was examined and promoted: and has since been well and in active service.

Case 7.—Cerebral Meningitis, Traumatic. In 1891, S. R., 32; brakeman; was admitted to hospital on account of chronic cerebral meningitis which had resulted from a lateral crush of head between cars three months before. He had been in another hospital during that period, and said that he had not had a half hour's continuous sleep during all that time, though had taken frequent and large doses of anodynes, etc. Along the sagittal suture and between it and the left parietal eminence there was so much hyperesthesia that the lightest touch of the finger caused intense pain. I treated him for a few days with various anodynes and had him watched closely, and it became evident that he could not be made to sleep longer than five or ten minutes at a time. I then had his head shaved, and tried galvanism, placing a large, light electrode over the sensitive part of head and an ordinary sponge electrode in left hand and turned on, by rheostat, a downward current of 2 ma. This was all he could stand, and at times during a seance of ten minutes, it became necessary to shift the head electrode. The current caused some immediate relief of pain and tenderness, and besides a feeling of numbness of left arm. The same treatment was repeated that day, with the same result, except that the relief of pain, etc., of head and the feeling of numbness of left arm lasted rather longer, about two hours, during which time he fell asleep in his chair—the first natural sleep after the accident. On the following day he could tolerate a little stronger current, 3 ma., though the current had to be temporarily reduced to 2 ma., during the seance, on account of severe burning sensation. The experience of relief of pain, and also the feeling of numbness again followed the treatment and lasted for a long time—three hours, and he again slept after the seance. Similar treatment was kept up daily and occasionally twice a day with similar effects. The only modification of application was the shifting, carefully, of the negative pole from

one hand to the other during seance, and in this way numbness of the left arm was prevented. The patient steadily improved: the current was gradually increased in strength: the hyperesthesia and pain became less and less, and the relief after seance gradually lasted longer, until in the course of a month he got sufficient sleep—three or four hours regularly after seance and some at night—without the use of any medicine. At the end of two months' treatment he was discharged cured and has worked steadily since.

Case 8.—Meniere's Disease. Last October Mrs. H., 26, married, and mother of two healthy children, and herself in apparently perfect health, consulted me about "ringing in ears and noises in head" particularly troublesome in the right ear, which had troubled her for two years, and which at times caused such confusion that hearing was difficult. She was examined by an aurist who expressed to me the opinion that the case was one of Meniere's disease. She had accidentally discovered that quinine would relieve her, but also, that when used daily for some time, it aggravated the trouble; so had come to use it only on occasions of social events. I gave her, with ordinary sponge electrodes, from ear to ear, a current of $\frac{1}{2}$ ma., delivered by rheostat, and reversed frequently during seance of five minutes, but reversed by changing the electrodes, as the shock of reversal by pole-changer caused pain. During the seance she expressed herself as somewhat relieved, and on the following day stated that the noises did not trouble her for two hours after seance. I administered the same treatment daily, except Sundays, for a month. The result of each treatment was nearly the same except that from day to day the subsidence of noises, etc., during seance was more and more complete and the after relief more and more prolonged. On two different occasions, however, I finished the seance with the positive electrode at the right ear, and upon her return after such treatment she complained that she had not received the usual benefit. On all other occasions I finished the seance with the negative pole at the right ear. At this time—after a month's treatment, she seemed quite well, except that after any unusual excitement there would be a temporary return of noises, etc. I now gave only three or four treatments a week until Christmas time, and for some weeks she had not had the slightest return of her trouble. I did not see her again until the middle of January of the present year, when she returned in almost the same condition as when I first saw her. I resumed the same treatment, with the same measure of improvement, and for a month she has had but two seances a week and has not had any return of noises, etc.

Case 9.—Abscess of Fallopian Tube. In December of last year Mrs. L., widow, 22, had her menses suppressed by cold and had pelvic cellulitis and evidences of the formation of abscess in the left Fallopian tube or ovary. After general treatment it was deemed proper by consultants to make a laparotomy, but she objected, and after washing out the uterus repeatedly with sublimate solution, though not finding any evidence of intra-uterine disease, the experience of Dr. Lapthorne Smith occurred to me, and I introduced a uterine electrode and carried its point to, and possibly engaged it within the left tube, connected it with the negative pole, placed the positive electrode in her hands and administered a current of 15 ma. carefully through a Massey rheostat for eight minutes. This caused considerable pain, and rather severe back pains followed the treatment and continued for about two hours when she suddenly got relief and this was accompanied by a profuse flow of pus from the uterus. From this moment she improved, and about the only other treatment given was a hot vaginal douche of 1 to 4,000 solution of sublimate, twice daily. The discharge of pus continued freely for about three days and then gradually diminished and in the course of three weeks ceased. She passed the time for her next period without menstruating, except to the extent of a mere show on one day, and then began to suffer pains and from abdominal tenderness; and it seemed that she was likely to have another attack of inflammation and supuration. Feeling sure now that the trouble came from stricture of the left tube I repeated the electrical treatment, but only using a current of 10 ma. eight minutes. This was followed by backache and increased soreness about the left ovary, but during the night her courses came on freely and she afterward had no serious difficulty and has since menstruated regularly, and is now in perfect health.

Case 10.—Suppression of Menses. On March 11 of this year Miss B. B., 20, consulted me at my office. Her menses had ceased suddenly two years before and had not returned, but she had had instead about once a month, a slight, thin, leucorrhœal discharge, preceded by such feeling as she had previously experienced at time of natural menstruation. She was emaciated, weak and anemic, but had no evidence of lung disease. She had been treated by two gynecologists who had

dilated the uterine cervix and had given her emmenagogues and tonics. Upon examination I found such stenosis of the cervical canal that it was with extreme difficulty that I passed the smallest uterine sound. The uterus was normal as to length and position. I was unable to pass the smallest electrical sound, so again passed the small uterine sound through the canal and connected it with the negative cord, and placed the positive electrode in the patient's hands, and turned on a current of 15 ma., and a bloody froth hydrogen gas mixed with a little blood oozed out, as usual, from the os. I moved the sound backward and forward constantly, during a seance of ten minutes and at the close it passed easily. The current was turned on and off slowly, and the patient felt no shock but experienced a slight burning sensation at her hands and some slight abdominal pain, and at the close of the seance complained of backache. It was nearly time for her monthly leucorrhoeal period. A week later she called and informed me that two days after the treatment her courses came on freely and naturally, and that she felt much better. Three days prior to her April period I gave her another electrical treatment like the first, except that I used a larger sound, and except that the current used was much weaker, only 8 ma. eight minutes. A week later she called again and said her menses came on time quite naturally. The stenosis of the canal had evidently been permanently relieved; she had some color; had gained in weight; was stronger and felt quite well. She has since remained well.

Case 11. Rheumatoid Arthritis. On March 20 of the present year I called on Mrs. L., 60, married, and mother of several married healthy children. Found her in a wheel-chair suffering from arthritis of the larger joints of the extremities; those of left side being most affected. She had been disabled for nearly two years and had not been able to walk a step, or lift an ordinary book, for over a year, and could not, on account of weakness of left knee, extend the left leg, nor on account of weakness of the wrists extend either hand. The muscles of the extremities were wasted and flabby, but her face had a good color; her mind was unimpaired and her appetite was good. She had been treated by several physicians, some of them eminent, and one had administered galvanism so strong as to be very painful, for a period of six months, but she had grown steadily worse. Beside such general treatment, similar to what she had previously received, I gave her galvanism daily for two weeks and since then have given her four treatments a week. The strength of the current has been uniformly 6 ma., as this is all she can comfortably bear. (In such cases, and in most cases I may say, I consider that a painful current is usually injurious.) The current has always been delivered with a rheostat: one electrode is placed at the feet: length of seance about ten minutes; during the first five minutes a hand electrode is moved over the spine with an ascending current for four minutes, and finishing with a descending current for one minute; then, during the last five minutes of the seance, the hand electrode is placed in the left hand with the right upon that, or both hands and wrists and occasionally both elbows as well are wrapped in a wet towel to which the hand electrode is applied, and for four minutes of this time the current is given in an upward direction and during the last minute in a downward direction.

This method fits my notion, and it fits the patient, for she is getting well. On one occasion I finished the seance with an upward current, and without the patient's knowledge; and that night she did not sleep and this was the only restless night she has had since I have attended her. The joints are gradually resuming their natural appearance and she is gaining strength and flesh. She can now extend the left leg and the right hand fully and the left hand nearly, and she can walk across the room several times unassisted, and can even walk down a few steps and seat herself in her carriage without assistance.

Case 12. Disseminated Spinal Sclerosis. On March 26 of the present year, I was consulted at office by E. H. W., 54, farmer and miner. He had some symptoms of disseminated spinal sclerosis, though the sensory tract was principally affected, yet there was slight paresis of extensors of all the toes and paralysis of the great toes. The upper and lower extremities were about equally affected, though the affection was most marked on the left side. With eyes closed, he could barely distinguish a knife from a piece of money in the right hand; but not one piece of money from another. With the left hand he could not even detect the contact of a knife or a piece of money or feel a lighted match until the skin was severely burned. He had slight ataxia, but, his patella reflexes were normal or slightly exaggerated. The first symptoms began last winter and consisted of pain, numbness and coldness of the extremities, difficulty of buttoning his clothes, liability of letting things fall from his hands, particularly from the left,

frequent stumbling and frequent attacks of insomnia and somnambulism. These symptoms increased until his sufferings were severe, and though he could walk about he had become quite helpless and could neither dress nor feed himself. His appetite remained good and his general appearance was fairly natural, though he was losing flesh rapidly—his weight having fallen in four months from 210 to 140 pounds.

Prior to this attack, his general health had been good, except that some three years ago he was troubled with dyspnea caused by aortic insufficiency, for which I prescribed iodid of potassium. In the course of a few months the cardiac murmur and the dyspnea nearly disappeared.

I now prescribed small doses of strychnia before meals, and small doses of codia for pain and restlessness; and administered a stable, galvanic current to hands and feet—10 ma. ten minutes daily, for a week, and since then three times a week. At each seance he was given ascending and descending currents, beginning with a downward current, reversing to upward, reversing to downward, reversing to upward, and reversing to downward. On two occasions, once experimentally and once by accident, the seance was finished with an upward current, and on the succeeding nights he was unusually nervous and restless. On every other occasion of treatment the seance was concluded, as indicated, with a descending current. The patient has steadily improved. There is now but little difference in the functions of the two hands, and with either he can detect by feeling different pieces of money, and can definitely locate a touch at any part of either foot, while formerly he could not detect a similar touch at either foot, and at dorsum of left foot could not even locate a pin prick. He rarely suffers now from pain or coldness, and has no abnormal sensations; can dress himself; sleeps better; walks much better, and is gaining strength and flesh, his weight having increased steadily at the rate of about two pounds per week.

Remarks—To further illustrate my view of the utility of galvanism in chronic forms of spinal disease, where the vessels of the cord in consequence of degeneration are becoming more and more incapable of performing their functions, I conceive that the electrical stimulus acting through the vasomotor nerves will, in the alternate use of the upward and downward current, not only fill and empty the vessels and thus materially influence the nutrition of the cord, but incidentally by dilatation and constriction restore the vessels themselves to their natural elasticity and use.

CONCLUDING REMARKS.

In closing I am constrained to say that the experience of the last year has confirmed my former opinion that electricity is as potent for evil as for good, and, like a toxic remedy for example, should always be used with discretion; or in other words, that it is never inert, even in small doses, and when not properly adapted to a case is necessarily injurious.

In presenting this paper, however, I wish to say, that I am open to conviction, and have studied the subject long enough to appreciate the remark ascribed to Edison, that "we do not yet know one-millionth of one per cent. about electricity."

THE HUMAN EPITRICHIIUM.

ITS PHYSIOLOGIC FUNCTIONS AND ITS RÔLE IN THE CAUSATION OF SKIN DISEASES.

Read in the Section on Dermatology and Syphilography at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY A. H. OHMANN-DUMESNIL, A.M., M.D.,

PROFESSOR OF DERMATOLOGY AND SYPHILOLOGY IN THE MARION-SIMS COLLEGE OF MEDICINE, ST. LOUIS.

There is no doubt whatever that the subject of histology is far from being exhausted and more especially in connection with development. Pathologic investigations, more especially in connection with bacteriology have, in later years, occupied so much of the attention of investigators that they seem to

have made the latter lose sight of the fact that we are not as yet thoroughly conversant with the morphology and development of normal structures and, as a natural result, histology has not advanced with the same rapid strides as other branches of investigation connected with the art of medicine. And yet, it is difficult to imagine a more fascinating study especially when it is taken up in connection with teratology and pathology, for in it lies that of which we are always in search—an explanation for the peculiar conditions or abnormal processes observed.

It may not be inappropriate to introduce the subject proper by a short description of the epitrichium. This layer of the skin was discovered and first described by Welcker.¹ In his examinations of the embryos of the bradypus or sloth he found it to consist of a continuous membrane which overlies the hairs, hence the name epitrichium from *ἐπι* and *τρίχινον*. This led to further investigations on his part and he found it to exist in various mammals and in man. The presence of this curious membrane in reptiles was clearly shown by Kerbert,² while Jeffries³ and Gardiner showed its presence in birds. These authors are not the only ones who have written on the subject but it seems to have awakened but little interest among dermatologists if we are to judge from their works. So far as I know there is no systematic treatise on diseases of the skin which devotes any serious attention to this particular subject and yet it is one of more than ordinary importance in the consideration not only of the anatomy of the skin but in the pathogenesis, pathology and treatment as well as prognosis of some affections of the integument. Nearly all the work in connection with the epitrichium has been done by pathologists and embryologists. It is for this reason that I propose to devote some little time to the consideration of the anatomy of the epitrichium such as I have found it in my investigations. I also desire to say a few words in regard to the physiologic functions of the epitrichium as this is also a subject not touched upon in the works devoted to physiology.

The epitrichium may be described, in general terms, to be a temporary epithelial layer of the skin which disappears at birth, the time when its functional necessity has disappeared. It overlies the stratum corneum of the epidermis and is anatomically as well as physiologically distinct. From the investigations which have been made by competent observers and to whom allusion has been made above, it is a structure which is not limited to mammals but occurs in birds and reptiles as well, and doubtless it also occurs in amphibians and fishes. This constancy of occurrence is a circumstance which should constantly entitle this little-known structure to more consideration not only at the hands of anatomists and histologists but especially of dermatologists. In this paper I propose to describe this structure in the human being only as an attempt; to do more would require too much space at this time and is certainly deserving of separate consideration in a paper devoted to the comparative anatomy of the structure.

I do not intend to trace the development of the epidermal system in the human being as it is much the same as in all amniota. Those who are doing so can consult Bowen,⁴ Minot,⁵ Zander,⁶ Curtis,⁷ Unna⁸

and others. In the human embryo the epitrichium may already be distinguished at the age of two and one-half months and from this time on it is not difficult to demonstrate its existence. It will be found to consist of one layer of cells with well-marked nuclei overlying another layer of cells which are flatter and provided with smaller nuclei, the whole resting on Bowen's basal membrane. As the embryo grows older the cells of the epitrichium grow flatter and larger and their contained protoplasm shrinks toward the center of the cells.

I have had occasion to make a number of preparations of the skin of embryos of various ages and taken from portions of skin removed from the scalp, behind the ear and from the groin. I have observed that at all ages from two and one-half months up to eight months the epitrichium could be made out quite distinctly. The cells in the younger specimens are larger and fuller whereas in the older subject they flatten, becoming fusiform in cross-section, but showing distinct nuclei, which are highly refracting and suggesting the presence of eleidin. In cross-section the stratum corneum can be made out as well as the stratum mucosum. The primitive arrangement of the cells and their grouping for the formation of the hair buds as well as the budding of the sebaceous glands is very plain. In the specimens from the older embryos the formed hair and the epitrichial cells which have been pushed aside by the growth of the former are plainly discernible. A horizontal layer of the integument, separated by macerating shows very plainly the presence of the epitrichial layer overlying that of the stratum corneum. At first the cells of the former are distinguished from those of the latter with difficulty but as development progresses the epithelial cells assume a more distinctly polygonal shape, the nucleus is more indistinct and the protoplasm concentrates, as it were, at its center. A certain amount of shrinking also takes place so that the cell is actually flattened despite the fact that the protoplasm has all gathered about one point. It is by no means a difficult matter to demonstrate the difference between those cells in integument derived from a fetus from six to eight and one-half months old. One prominent feature is that the cells of the epitrichial layer are much larger than those of the underlying structure and this disparity increases with the progress of development.

An interesting question arises as to whether the epitrichium finally merges into the horny layer or not. This idea has been advanced by some very competent authorities, but it is open to serious objections. If it becomes a part of the horny layer it should certainly be so already at the time the hair emerges from the skin and yet it is not. It is raised up by the growing hair. Furthermore, the cells of the epitrichium never become perfectly flattened like those of the horny layer and are essentially of a different nature morphologically, histologically and chemically. Moreover, it can be separated from the horny layer at any period and this separation occurs at or about the time of birth, so that a consolidation of the two seems hardly probable.

To attempt an explanation of the physiologic func-

tions of the epitrichium is by no means an easy task, and that it possesses such there can be no question or doubt. It may be argued that it is simply a persistence of a type, but this is simply an explanation which does not explain, for even if it be such in man it must have some function in animals. In the bradypus it is much more developed and is separated from the embryo, thus constituting another amnion it is claimed. But, it may be asked, of what utility would such another amnion be? From an examination of this peculiar membrane it would seem that it is impermeable to water—at least it does not take up aqueous stains very readily, and from this the conclusion might be drawn that its function is to protect the skin from maceration through the action of the liquor amnii. And if death of the embryo supervene maceration will take place, although more slowly than when denuded skin is placed in water. This prevention of maceration is aided by another condition, viz., the retention of sebum upon the surface of the skin, and this is effected by the limiting action of the epitrichium which overlies this sebum or vernix caseosa which has formed. If this fat be carefully removed from the skin of a new-born infant and its covering membrane be carefully mounted it will be found to consist of a single layer of cells having all the characteristics of the epitrichium, which naturally leads to the conclusion that a complementary function is to retain the sebum and thus act further in preventing maceration.

A question which naturally suggests itself in connection with the epitrichium is in regard to the length of time which it persists, and as to whether it is cast off, and if so, at what period of fetal life does this occur? As the embryo increases in age the cells of the epitrichium become flattened and in this process the outlines become polygonal and the edges closely adherent to one another. This change takes place at those parts and at the time that the hairs and sebaceous glands assume form and the cells composing their first buds group themselves in a definite manner. As is well known, the development of the hairs and fat glands is rapid, so that by the time the shafts of the former emerge and the secretion of the latter finds its way to the surface the epitrichium has become a single, continuous, definite membrane composed of one layer of flat epithelial pavement cells rather large but quite resistant. In the locality where the hair development is strongest, such as the scalp, the epitrichium is first raised and in those places where the secretion of fat is most active it is resisted to the greatest degree. Where neither hairs grow nor sebum is secreted there is apt to be no separation at all, and this is best exemplified in the case of the nails. The eponychium, from *ἐπί* and *ὄνυξ*, as Unna has demonstrated it, is analogous to the epitrichium and may be found in earlier fetal life. Later on it disappears having, in all probability, been cast off in the course of the growth of the nails. The fact that the epithelium is found over the entire integument in earlier fetal life and that it becomes gradually separated in the later life of the embryo, is evidence of the fact that it is finally cut off at that period when it is no longer physiologically necessary. Furthermore, the fact that even at birth it may be found overlying the accumulated secretion of sebum is further evidence that the final casting off is a comparatively late process.

From the fact that, in the early fetal life the epi-

trichium can be easily demonstrated in the embryo, and furthermore that it is a distinct structure composed of a different sort of cells from those which form the outermost layer of the stratum corneum. In early developmental life it is closely adherent to the underlying layer of cells, but later on it separates in the manner which has just been given. But, should there be an arrest of development of the hairs and sebaceous glands the rising up of the epitrichium does not occur and this membrane adheres to that overlying the stratum corneum and does not become separated from it for a period of time almost if not coincident with birth. In the meantime the developmental impulse which should have expended itself upon the hair and sebaceous glands is diverted to the horny layer, and it undergoes a rapid and marked multiplication of cells, making it thicker and assume a horny appearance. That the epitrichium does not become a component part of the stratum corneum may be easily demonstrated by means of selective stains which will decolorize in the cells of the epitrichium and will not in those of the stratum corneum. A question which suggests itself in this connection is as to whether the thickening of the horny layer is due to a persistent adherence of the overlying membrane of which we are speaking. It is evidently not, but depends rather upon the arrest in development of the hairs and sebaceous glands, and this arrest is possibly dependent upon pressure exercised from without, which condition would also act as an important factor in producing an adhesion between the epitrichium and the stratum corneum.

When the process is one which is generalized the thickening of the horny layer is so also, and in consequence we have the different varieties of ichthyosis known in xerosis, ichthyosis simplex, and ichthyosis congenita or so-called harlequin fetus. These are simply different varieties of the same process, whereas ichthyosis hystrix and ichthyosis sebacea are somewhat analogous but have superadded an exaggerated secretion of sebum. But it must certainly be true that the ichthyotic process owes its origin to the same causes that the other forms do, and there is added thereto a certain development of the sebaceous glands, whose functions not only continue but are exaggerated by the stimulation exerted by the pressure due to the thickening of the stratum corneum. In all of the former ichthyotic conditions there is evident lack of development of the sebaceous glands, and in all forms of ichthyosis there is a deficiency in the number as well as size of all the lanugo hairs. The skin is harsh and dry or rugous and spinous, and it persists in this condition despite the best directed treatment, which can only mitigate it at best.

Should the epitrichium be adherent in localized areas only, we have as a result a localized and limited ichthyosis which does not extend beyond its primary limits. A peculiarity observed in connection with localized ichthyosis is the fact that it partakes of the nature of the portion of integument which is affected. If it be in the palms and soles the thickening is much greater than if it occurs upon a flexor surface, and upon this latter it is never as well marked as upon the extensor portions of the integument, as is daily shown by observation. A peculiarity which has been noted in connection with both localized and generalized ichthyosis is the fact that it rarely if ever affects the face and axillæ. This is explainable by the further fact that in these localities the sebaceous glands

develop early and rapidly and attain a comparatively large size, as they also do in connection with the hair of the scalp, this latter being also singularly free from the ichthyotic process.

From an anatomic examination of the epitrichium in its different stages and from a critical examination of the various points involved in the question, it seems to me that there can be no doubt whatever that the epitrichium plays an important rôle in connection with the development of the human integument. It not only does this but it plays a by no means insignificant part in the production of some keratogenous skin diseases, and it is far from improbable that lichen pilaris is in some way indebted to the same structure for its origin. There are other processes of a similar pathologic nature which certainly should be investigated more closely. Like ichthyosis they are of frequent occurrence and much more common than is usually supposed, so that investigations of a thorough and convincing nature could be easily made. No attempt to include any considerations of this kind would be in order at this time in this paper, as it is the intention of the writer to deal only with general considerations, especial ones requiring more space than could be given at this time.

An explanation for the existence of the diseases of the skin which have been alluded to has been attempted by various authors, but it is one in which no satisfaction can be found. It is that ichthyosis is hereditary, and this assumption is based upon observations of one ichthyotic parent having one or more children similarly affected, or the condition being seen through several successive generations in members of the same family. It may be possible that an anatomic peculiarity is transmitted from parents to children, but that a pathologic process may be is a proposition repugnant to reason. If we assume that an anatomic peculiarity is transmissible from parent to child we can readily understand that an arrested or incomplete development or an exaggerated development may occur and, in connection with the subject under consideration, there could occur a transmission of the developmental peculiarity in the sebaceous glands whereby they would not attain their proper form, size and secretory functions, thereby permitting the epitrichium to adhere to the stratum corneum and this, in turn, act as the active cause of ichthyosis and allied conditions. This might be taken as a partial explanation, but the subject is so extensive that each portion of it, from its very nature, should be taken up separately and be thoroughly discussed.

THE THERAPEUTIC ABUSE OF OPIUM.

Read by Title in the Section on Materia Medica and Pharmacy at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY G. WALTER BARR, M.D.

PROFESSOR OF MATERIA MEDICA, THERAPEUTICS, ETC., IN THE COLLEGE OF PHYSICIANS AND SURGEONS.
KEOKUK, IOWA.

While the writer desires to be enrolled among the conservatives in the midst of the present enthusiasm regarding the newer materia medica; that is, among those who insist upon rational evidence and clinical proof to a critical degree before a verdict in favor of some new chemical compound is added to the certainties of our therapeutic knowledge; yet it seems to him that in one direction at least there is too much

leaning upon the old standards. While our knowledge of pathology and physiologic action has long since passed the point of the treatment of symptoms, yet we still cling to one drug which does most of its work in relieving symptoms only. Of course a drug which has the dynamic energy of opium must always be an equally potent power for therapeutic good; but it is not what can be legitimately done with opium, but what is actually done that is the subject of this paper. The present purpose has nothing to do with drug habits and the curse of morphinomania which to-day is probably doing more harm in the United States than alcoholic intemperance is to be properly charged with. The writer believes that the medical profession as a whole, and of course with shining exceptions, is still too prone to use opium as our grandfathers did and that the equipoise between pathology and the dynamic effects of the drug is as a matter of fact a thing to be sought after to-day rather than a thing which is.

Chemically and physiologically opium is perhaps the most complex drug in the pharmacopœia. It contains a large number of active principles which have been certainly isolated; a number more that are probably present in the crude drug, but claimed with some reason to be merely products of chemic manipulation; and also may contain some not yet identified as chemic entities by laboratory research. It seems a little strange that with the present tendency toward the use of drugs uncombined with others in one prescription, so many active principles should be so often prescribed at once under the title of opium. The retort that the drug opium has its own physiologic action which is well known from years of experiment, clinic and otherwise, will probably not be heard from one who has taken pains to ascertain definitely and exactly what we know of its dynamics to-day. That the combination of so many active principles has, by virtue of the correlation of physiologic forces, a dynamic action of its own goes without saying; that this action can not be prognosticated with much certainty is proven by the large number of cases of alleged idiosyncrasy in evidence. That opium is of great therapeutic value is claimed at the outset; that it is over-rated is also contended.

When the natural polypharmacy of opium itself is avoided, the resort is nearly always to its most active constituent, morphin. As a matter of observation, and one of those things which can hardly be proven, the number of physicians, East and West, who prescribe or leave a single dose of morphin as part of the first treatment for anything from acute alcoholism to typhoid fever is greater than should be told except under the rose. The patient soon feels better from the stimulant and perhaps rests quietly later from the after depression. The patient is fooled, the friends are fooled, and too often the physician is fooled, into believing that the net results of morphin were beneficial. It is not necessary to discuss the real value of this routine practice which generally retards recovery for several days or a week. The effects of morphin upon the secretions, metamorphosis and the disposal of waste products are exactly what is not desired in most cases of disease. Yet morphin is usually chosen to produce certain effects upon the nervous system without regard to its energetic action in other directions. For many of these effects some other drug which has not the disadvantage of morphin may be chosen. For pain, either

acetanilid, antipyrin, aconite, strychnin or codein will often be as efficient, if the drug be chosen to fit the pathology present, and none of these do as much damage while they are relieving the pain as does morphin. Codein is being substituted for morphin in these later days to a gratifying extent, but is not yet fully appreciated. The writer is thoroughly satisfied that it does not produce a habit even in highly sensitive neurotics, and that it acts with little energy upon the digestive tract and heart. As a somnifacient morphin has been nearly driven out of use by the products of the modern chemist, and in other fields also should be discarded. As a cardiac stimulant, morphin acts quickly and usually energetically it is true; but the after-depression which always comes after a dose of morphin may be avoided by using instead the invaluable strychnin, the swift glonoin, the energetic caffein, the powerful digitalis, or even the treacherous atropin in proper dosage. To use morphin or opium for a condition of nervous excitation and exalted reflexes is in many cases like stunning a refractory patient with a club. Valerian, the bromids and hyoscyamus will generally give better therapeutic results of greater permanence and with less risk.

It is in those diseases of the digestive tract which are most common in summer that opium is the medium of most harm. After all that has been written about washing out the intestines with solutions of various antiseptics, many practitioners have not relinquished the mental association of diarrhea and opium which was almost universal a half century ago. Whether one believes in rational medicine or in statistical empiricism, close observation must drive him to the conclusion that very rarely indeed is opium indicated in the treatment of diarrhea. The trouble is that here the symptom overbalances the pathology in psychic impression on both patient and physician, and symptomatic treatment still survives to a very considerable extent. Without going into detail as to pathology, it may be said that a diarrhea needs usually some drug which increases the excretory functions and thus drives out of the body something which by its presence is producing the flux from the bowel. Salol and other antiseptics by the mouth; various solutions injected to flush out the intestinal tract and make it bacteriologically clean; a saline cathartic; a cholagogue and especially one acting also on the other secretions of the digestive apparatus; camphor, aromatics, the bitters and the digestive ferments—these medicines, all of which exert a dynamic energy in exactly an opposite direction from opium, effect a cure in much less time than does the latter. Of course opium temporarily relieves the chief symptom at once; and when its influence has subsided and the disease still persists the condition is called a relapse or a new attack.

The writer knows that he is writing what to some are platitudes; he foresees that the criticism will be made that he is fighting an immaterial ghost. And yet, craving the indulgence of those who do not offend the genius of rational medicine in the ways mentioned, he has been driven to writing this paper by observations upon the practice of really excellent physicians and by noting the frequent recurrence of opium, laudanum, deodorized tincture of opium and morphin¹ in the prescriptions filed away by the phar-

macists. The farther the investigations were carried the greater became the divergence between the teaching of modern medical science in school and book and journal and the practice of the profession at large. While we are making such great additions to our armamentarium, it is not unimportant that we throw away some of the old weapons which have been rendered obsolete by modern ideas and which have become merely impedimenta.

It goes without saying that opium has a real value therapeutically in certain inflammations, great pain, rare forms of diarrhea, as a splint for the intestines and in some other directions. Abuse does not imply absence of use.

THE DANGERS OF SYPHILIS AND HOW TO AVOID THEM.

Read in the Section on Dermatology and Syphilography, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY ALGERNON S. GARNETT, A.M., M.D.

HOT SPRINGS, ARK.

I do not feel that an apology is necessary for briefly calling the attention of the profession to the necessity for greater care and honesty in dealing with syphilis and its dangers. No disease is so universally distributed and none which is so insidious in its invasions, even into the ranks of the most innocent. I do not believe that there is as much candor displayed in discussing this disease as its gravity demands, and that by our silence and easy acquiescence in the mistaken idea of its harmlessness, after a year or two of treatment, we are adding to the burdens of mankind. The dangers of syphilis are most frequently its remote effects, the immediate symptoms, such as chancre and the lesions of the skin and mucous membranes passing away quickly under appropriate remedies. We find the remotest effects in all the different forms of paralysis, locomotor ataxia and insanity. The insidious microorganisms have worked the destruction of the nervous system, while the surgeon was watching for an outbreak. The quick subsidence of the external or objective symptoms of this disease misleads the patient and the doctor, and has induced some of the most distinguished men in the profession to declare that it was benign and self-limiting, that it would expire by the statutes of limitation if let alone.

In the same catalogue should be placed those rhetoricians who believe or so state that a year or two of mild treatment will cure syphilis and enable the patient to marry without apprehension. These grave blunders are helping to reverse the conditions favorable to the higher development of the human race and handicap it with leprous diseases, which would not be allowed perpetuation in the lower animals under our control. False sentiment should have no standing in our profession, whose influence should be wielded for posterity, so defenseless against its cruel parents.

How can we measure the duration of diseases induced by microorganisms, which may sleep for years before wakening to a destroying activity? It is a well-known fact that the lower organizations will

¹ In the country the use of opium has not decreased; and in the city it has lessened *except* in diarrhea prescriptions; morphin has increased in both city and country in physicians' prescriptions and bedside use, especially hypodermically and by recent graduates. A great deal of certain proprietary "substitutes" for opium which are really the deodorized tincture is used in the West. In the paper "opium" means any preparation of the crude drug.

¹ Careful inquiry among pharmacists, druggists in towns, and small wholesalers selling to doctors direct, brings the universal response that

live in a state of inactivity for years. It is this phase of the subject that should make us hold every case of syphilis *sub judice* for years, at least seven. I do not advise active treatment for that period, but after the first three years of active treatment with mercury, a mixed treatment during a month twice a year for three years more, will serve to prevent any further destructive action in ordinary cases.

The purpose is to keep the disease and its manifestations subjected to remedies. The absurd belief entertained by many, that mercury produces paralysis and locomotor ataxia, has been so often controverted in my experience that I would not discuss this feature of the subject, were it not for the grave injury which it is doing. I am treating now patients with locomotor ataxia and in nearly every form of paralysis, to whom I am giving maximum doses of mercury with the best results. This has been my experience for a number of years. My observation has been that nearly all the cases of syphilitic paralysis have been due to treatment for too short a period, or that there never had been a full mercurial effect produced. I feel quite sure that I shall be sustained in this statement by every close observer of the phenomena of this disease. In my discussion of the proper treatment I assume that all other indications have been filled; that the patients have lived soberly and carried out intelligent hygienic rules for their guidance. Had the theory that mercury produced paralysis been verified, the syphilitic paralytics whom I have treated during the last twenty years would have succumbed to the mercury which I gave, as I am very generous in my prescriptions. It seems to me to be a logical conclusion that syphilis is due to a protozoon, a microörganism, a living entity. The whole theory of treatment is to kill this living germ without killing the man in whom it is existing. So far progress in medicine has not discovered anything better or so good as mercury with which to combat its injuries and to limit its existence.

As the objective of all treatment is to poison the specific germ, and at the same time render the patient unfit for its abode, it follows that the greater the quantity of mercury that can be introduced, without danger, the better the protection given. The action of mercury is directly as a poison and indirectly as a tonic, in other words, when the microörganisms are killed or weakened, the system will re-assert its normal vigor.

If syphilis is due, as is now believed by scientific men everywhere, to a protozoon, it would account for many cases of attenuated inoculations which do not give the characteristic symptoms and features of the disease that we are accustomed to recognize and which render our diagnosis difficult.

Many years since, Kassowitz, of Vienna, who had charge of the hospital for syphilitic women and children, stated that he frequently met with women married to men in the later stages of syphilis (and who had been previously healthy) cachectic and de-vitalized, without showing any other symptoms of a specific contagion, and yet who failed to improve under any other than specific treatment. He believed that in many cases a married life between a man with tertiary syphilis and a perfectly healthy woman would be followed by the loss of strength and vitality to the latter.

While my own experience does not confirm his in many particulars, I have seen so many suggestive

cases that I feel as if I were leaning to virtue's side when I discourage marriage in all syphilitics who had not been treated for many years and who were not leading a life conforming to the laws of hygiene.

There is an obligation on the medical profession to see to it that the progenitors of future generations do not hand down diseased bodies and minds. This responsibility should not be ignored, however great the temptation to popularize ourselves by pursuing a different course. Let us guard the race by establishing a quarantine against all contagious diseases. To prevent the crime of the marriage of syphilitics, *in the earlier stages*, would it not be commendable to have a law requiring a health certificate from a board of examiners accompany every marriage license?

Very candidly and frankly, I see no hope for the syphilitic at present except in mercury and the iodids, although I fully believe that the day is not far off when some virus will be used for inoculation, which will relieve mankind of the frightful results of this malady. Experiments with horse serum are in the right direction.

THE NEW SURGICAL SPLINTING.

Read in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY EDWARD A. TRACY M.D.

MEMBER OF THE AMERICAN MEDICAL ASSOCIATION.
BOSTON, MASS.

Two years ago at the Milwaukee meeting of the Association, I had the honor to read a short paper entitled "A New Material for Surgical Splints and Spinal Jackets, with a Method for Applying It." A few months later I read before the Pan-American Medical Congress held in Washington, a paper entitled "A Brief Splint-Technology for Surgeons," in which has been outlined a scientific system of surgical splinting. As a small contribution to the filling in of this outline I shall present to-day four new splint forms and report cases illustrating their use. Before presenting them to your consideration, permit me to speak for a moment of the material used in their construction. It is composed of crushed wood-fiber, rolled in a rugose fashion, and in which a fabric is incorporated during the rolling process. The material is the result of original experimental work, having for its object the attainment of a moldable material that would comply with the requirements of a scientific method of surgical splinting. The experimentation was done by me for the most part in a pulp mill, the use of which was courteously placed at my disposal by my kind friend, Mr. Charles H. Fish, of Manchester, N. H. The material and method of splinting as presented to you, represents the practical solutions of the several problems met by me during the progress of my work, problems relating to the toughness, plasticity, rigidity and technical manipulation of a splint material having for its basis wood-fiber. None the less do I believe that the work presented to your consideration will seem admirable for its simplicity.

Having considered the splint material, allow me to describe briefly the ordinary manner by which I make from it a splint. The first thing to be done is to cut the splint blank from a sheet of the material. The outline for this blank can readily be gotten for the ordinary leg and arm splints, by simply placing a sheet of the material against the limb and pencil-

ing the outline directly on it. In other cases a pattern of the splint blank can be made by cutting a piece of paper the proper shape to enfold accurately the part it is desired to splint, and then laying this paper pattern on a sheet of the material and penciling the outline of the pattern on it. By following the outline, the splint blank can be cut from the material by means of a jack-knife or a pair of shears. A suitably shaped blank having been cut from the material, it should be moistened so as to become plastic or moldable. The moistening can be done with water, but it is better to moisten the blank with a solution of potassium silicate. The ordinary solution sold for surgeons' use and further diluted with half its bulk of water I find serves admirably. This solution adds considerably to the rigidity of the splint. It is also an antiseptic. The moistening is best done by painting the solution first on one side of the splint blank and then on the other side, and so on two or three times, using for the purpose an ordinary flat paste brush. The splint material will be seen to absorb the moisture, and after a minute or two will become quite plastic or moldable. The blank should then be applied directly to the limb and a roller bandage snugly applied over it so as to make it conform to the shape of the part we intend to splint. The blank should be carefully removed and dried over a kitchen fire, gas stove, gas jet or other sufficient source of heat. While it is drying the splint should be watched and helped, by holding it properly, to retain the right shape. Before it is completely dry, it should be applied to the limb for a moment and, if need be, corrections made, before complete drying permanently fixes its form. The drying of the ordinary splints averages from ten to fifteen minutes. A single layer of merino (to be had in most households from an old garment of underwear) or a few layers of gauze is all that should be placed between the splint and the skin when applying the splint to the case for which it has been made.

In many cases of simple joint fixation, if the proper thickness of the splint material be used, (it is manufactured in sheets of three different sizes by the American Wood Pulp Company, of Boston.) the splint blank can be molded over the parts and a bandage applied directly and the splint allowed to dry on the limb without removing it. The four splint forms which I shall here describe have been chosen because of their utility, simplicity, and to suggest to you the scope of the new splinting. I am sure that the practitioner who devotes a little attention to them, or even to the first splint form to be described, will be rewarded with the result. These forms can serve as an introduction to the use of my splint material and after familiarizing himself with its characteristics the practitioner will be enabled to work it into such forms as the indications met with in any given case may call for. This mastery of the material is readily attained by the careful practitioner. But should he not care to push his conquest of it further than these simple splint forms, I repeat, the time so spent will repay him, and he will be surprised at the readiness with which he can get an efficient fixation of the knee, elbow, ribs (as much as the anatomical conditions of the ribs permit) or hip. The esthetic feature of the new splinting, both of color and form, and its comfort to the wearer by reason of its lightness, I shall but mention; they are best appreciated by the patient.

A LATERO-POSTERIOR KNEE SPLINT, FOR FIXATION OF THE KNEE-JOINT.

The pattern for this splint should be cut so as to embrace the posterior and one of the lateral aspects (preferably the inner) of the thigh and leg, extending from well up the thigh to a few inches from the ankle. Following this pattern for a guide, the splint blank should be cut from a sheet of the splint material having a thickness of about 2mm. The splint blank should be moistened, molded and dried in the usual manner before described. This splint well illustrates the mechanical principle by which the breaking strain of any piece of flat material is greatly increased as it is made to assume the tubular form, or by having a flange in its form. A piece of the splint material of the thickness described, molded over the posterior aspect of the limb only, could not be expected to serve for the fixation of a joint con-

FIG. 1.—A Latero-posterior knee splint, left.

trolled by such powerful muscles as in the knee. But by simply widening the blank so that it can be molded over a lateral aspect of the limb as well as the posterior aspect, the needful element of tensile strength is increased in far greater proportion than to the extra amount of the material employed. Another advantage is that the splint so molded and applied to the limb can not move from side to side; its flange molded over the side of the limb prevents this; it therefore gives a fixation superior to any posterior or ham splint. This splint is illustrated in Fig. 1, which is taken from a photograph of one molded on a patient (J. W., aged 53) by me at the Boston City Hospital (by courtesy of Dr. Thorndike). The case was acute exacerbation of a chronic synovitis of the left knee. The splint was worn three weeks with satisfactory results. At the same hos-

pital I treated a young man with an acute synovitis of the right knee, of traumatic origin. There was considerable effusion into the joint. A similar splint was molded on the patient's limb and worn for eight days. The effusion and tenderness had then disappeared; the patient was ordered to use the limb carefully, and to return to his organ studies. He did so without any recurrence of the trouble.

AN ELBOW SPLINT (EXTERNAL) FOR FIXATION OF THE ELBOW JOINT.

This splint serves for fixation of elbow joint and as it does not impinge upon the internal aspect of the joint allows a ready inspection of the internal condyle without the necessity of removing the splint. It is of easy construction. A pattern of the splint blank is cut so as to embrace the flexed arm and forearm; the upper part from the fold of the axilla to that of the elbow, the lower part extending from the olecranon and fold of the elbow to the knuckles of the hands, the arm being semi-pronated. The pattern should be cut so as to fold over or embrace the ulnar side of the forearm and hand. Following this pattern for a guide, the splint blank should be cut from a sheet of the splint material having a thickness of about 2 mm. It should then be

FIG. 2.—An external angular elbow splint; left arm. View is of the outer aspect.

moistened, molded and dried in the ordinary manner before described. The slight redundancy of material found near the olecranon when molding the blank should be pinched up between the fingers and bent over so as to lie against the splint. This splint is illustrated in Fig. 2, taken from a photograph of a splint molded by me on the left arm of Willie M., a boy who was brought to my office with a backward dislocation of the elbow and a fracture of the internal epicondyle, caused by a fall from a height of about five feet. I reduced the dislocation and molded the splint in accordance with the technique given above, and bandaged it to the arm, leaving the internal condyle exposed to sight. I then placed a cloth compress over the internal epicondyle and bandaged it so as to retain the fragment in its proper position. After six days the splint was removed daily so as to exercise the joint with gentle passive motions, and after eleven days the splint was omitted entirely. On the twentieth day all motions of the joint were normal, except extension, which was slightly limited. The boy then disappeared for awhile, and when next examined, three months after, nothing abnormal

except a very slight obtundity of the internal epicondyle could be detected; all the motions were perfectly normal.

A similar splint was employed in the case of A. N., an old man treated by me at the Boston City Hospital (by courtesy of Dr. Thorndike). The case was a fracture of the right ulna at its middle third, caused by the kick of a horse. The fixation of the fragments was attained by this splint supplemented by a palmar splint extending from the elbow fold to the wrist. In seventeen days there was union; on the twenty-first day the angular splint was cut across below the angle of the elbow, so that it became a simple dorsal forearm splint, leaving the elbow joint free. For safety this splint was left on for eight days, and after twenty-nine days from the beginning of treatment the patient was discharged well, with normal mobility to the arm and forearm, and but a moderate callus. The indication in this case, complete immobilization of the ulna, was read-

FIG. 3.—A splint used in a case of rib fracture; left. A front view of the splint.

ily met by fixation of the elbow joint and of the wrist joint by aid of the lateral angular splint and boxing in of the forearm by aid of the palmar piece from the elbow to the wrist. The result was considered excellent considering the age and condition of the patient (about 70 years, and with a double cataract and atheromatous arteries).

A SPLINT FOR RIB INJURIES.

This splint is a very simple one and readily constructed. It should be molded over the injured side of the chest, from an appropriately shaped splint blank. The blank varies in shape according to the situation of the injury and also to the fact of the chest being that of a male or female. These slight variations of shape need not be detailed, as they will readily suggest themselves for the case under treatment, when the principles governing the treatment are understood. Fig. 3 is from the photograph of a

splint molded over the chest of Mrs. C., aged 58 years, treated by me for fracture of the eighth and ninth left ribs. The splint was worn twenty-one days, being easily retained in position by a snugly applied swathe, to which was applied a shoulder strap consisting of a piece of cotton cloth held by safety pins, over the left shoulder. This method of treatment for the ordinary case of fractured ribs seems a rational one. I do not understand how adhesive plaster, or a simple swathe can protect the broken bones from external pressure that may occur at any time, and particularly when the patient sleeps. The rib splint, however, spanning the weakness in the chest wall and resting on the secure foundation of the sound ribs, prevents undue pressure from reaching the point of fracture. This, doubtless, explains the comfort with which the splint is worn. Moreover the indication to limit motion in the affected side is effectually met by a properly constructed splint molded so as to fit the half chest in the position it assumes on forced expiration. The splint thus made tends of itself to hold the half chest in that position, and its efficacy in this respect is perfected by the swathe with shoulder strap attached as described, which maintains it in position.

A HIP SPLINT.

This splint furnishes a ready method for obtaining an efficient fixation of the hip joint without the extraneous aid of blacksmithing or special tools. A pattern should be cut so as to extend from an inch or two below the axilla to about the same distance below the knee. The posterior border of the pattern commencing at the upper border should follow near to the spinal column, and over the buttock down the posterior and inner surface of the thigh to the inferior border of the pattern below the knee. The anterior border of the pattern commencing at the superior border below the level of the axilla, should pass over the chest and belly near to the middle line of the body, striking off below the umbilicus to cross the lower third of Poupart's ligament and down the inner surface of the thigh to end at the inferior border below the knee. Following the pattern for a guide the splint blank should be cut from a sheet of the material having a thickness of 2 mm. This splint blank should be moistened, molded and dried in the manner described above. Another blank should now be cut from a sheet of thinner material, and it should be moistened in like manner and molded over the other one so as to serve as a reinforcement. The two forms should be laid together as one, with a layer of liquid glue between them, and applied as one to the limb. While molding this splint the patient should be laid on his back with the limb extended in a line with the body. The moistened blank should be bent so as to embrace the affected thigh and side, and molded over the parts by means of a roller bandage. The splint should be finished by binding its border with strips of chamois skin fastened on with a cheap liquid glue. Immediately after binding the splint it can be applied to the patient, the glue setting as well with the splint in position. This splint should be properly bandaged to the body if we desire the maximum of hip fixation. This is done by taking a few tight turns around the hips with the roller bandage and then bringing the roller down so as to embrace, in figure 8 style, the upper portion of the affected thigh and the opposite hip. A bandage

should then be applied from the lowest portion of the splint, embracing first the knee and thigh, then the hips and finally the chest. The bandaging can be prevented from slipping by pinning together the layers of bandage where they overlap. The splint illustrated in Fig. 4 is taken from a photograph of a splint molded by me on Cornelius O'H., a boy aged 8, with hip joint disease of the left hip. Night cries and pain ceased shortly after its application. In three weeks the boy was enabled to be up and out by means of crutches and a raised shoe. After four months, tenderness on deep pressure over the capsule of the joint had somewhat diminished, but flexion and outward rotation were considerably impaired. The splint was worn for eleven months with no setback to the improvement of the patient. The parents of my patient then insisted on the withdrawal of all treatment, crutches, raised shoe, and splint. At that

FIG. 4.—A hip splint; left. View is of the posterior aspect.

time there was a slight limitation to flexion, the left gluteal fold was absent, and considerable atrophy of the left thigh present, though not as much as six months before. I warned the parents as to the probability of their being trouble in the joint, but their determination to have the boy use his limb remained unchanged. They promised me to watch for symptoms and on the first appearance of a limp or pain to resume treatment. There has been no recurrence and now (April 27), seven months since omission of treatment, upon examination I find his gait, walking and running, normal. No atrophy of thigh or leg. Gluteal fold present, no tenderness of hip joint. All motion except extreme flexion of the thigh normal. Upon extreme flexion the pelvis moves with the thigh bone, though no pain is felt. The boy has been attending school since January, and is as full of life on the streets as any of his comrades. [Jan. 14,

1896, over fifteen months since omission of treatment, the boy is as well as ever.]

It needs but a little consideration to understand the thorough fixation procured by this splint when correctly applied. A cursory examination will show that adduction, abduction, extension and flexion and their combination, circumduction, are out of the question with this splint in position. It is left only to consider the remaining motion of the hip joint—rotation. It is prevented by the grasp which the splint maintains on the knee, and also by its forward pressure on the great trochanter. The trochanter, it will be remembered, swings backward in an arc on outward rotation of the thigh.

In concluding my paper I will remark, that because of circumstances not controllable by me, the splint material has not been accessible to you all, and therefore you can not testify to the advantages of the new method of surgical splinting from personal experience with it. It gratifies me exceedingly, however, to be able to refer to Dr. George W. Gay, of the Boston City Hospital, who wrote in a note to me last November: "You may quote me as being favorably impressed with your surgical splinting after a considerable personal experience with it." The object of my work in surgical splinting is to emphasize the practicability of living up to the principle of surgical practice enunciated by Dr. H. O. Marcy: "The surgeon must make a splint to fit the limb and not the limb to the splint." I believe, now that the splint material is accessible to the general practitioner, that the method described, will result in the completion of a scientific system of surgical splinting that will do honor to our Association and our country.

NOTE.—Since reading the above paper I have done considerable splinting, including cases of hip, knee, and ankle joint fixation, Collis' fracture, using only water as a moistener, and allowing the splint to dry in position on the limb. In several cases absolutely nothing was placed between the limb and the splint, and though the splint was worn for several weeks no excoriation of the skin occurred. The object of this note is to emphasize the simplicity of the technique now employed—water alone being found essential, the drying of the splint off the limb, and the use of a silicate solution being unnecessary.

99 Broadway, Boston, Mass.

SOME REMARKS ABOUT ASEPSIS IN MILITARY SERVICE.

Read at the Meeting of the National Association of Military Surgeons, Buffalo, May, 1895.

BY LIEUT.-COL. EDWARD BOECKMANN.

ASSISTANT SURGEON-GENERAL OF THE MINNESOTA NATIONAL GUARD.

It is with some hesitancy that I venture to bring such a worn-out topic as asepsis before this distinguished assembly, which is represented by our foremost bacteriologists, our best surgeons and by men who, perhaps, daily have opportunity to rejoice in the good fruits of their aseptic efforts. But when I at the same time consider that the last word on asepsis has not yet by any means been spoken, that our views are subject to change and our opinions vary, that there yet prevails considerable difference and even uncertainty with regard to the value of the different means and apparatus of disinfection, that daily, partly through ignorance and partly through negligence, violence is done to the simple but strict laws of asepsis, and that we military surgeons, because of the peculiar and difficult conditions under which we must exercise the aseptic art in service, particularly should be conversant with the principles of asepsis.

I certainly need no apology for presenting that which at first sight appears to be A, B, C to us all.

Our surgical enemies, which all of us know so well, either through our practice or through our books, and which are distinguished by their ubiquity and numbers, less by their tenacity of life, we endeavor to keep at a distance in different ways; we destroy them, we remove them or we render them innocuous. Could we simply destroy them all this would be the most ideal procedure, but since this, unfortunately, is impracticable, we must in every case avail ourselves not only of the chemic means of disinfection, which are the proper germicides, but also of mechanical and chemic measures whose usefulness consists in the removal and the inhibition of the growth of microorganisms.

MECHANICAL DISINFECTION.

Since we can not boil our hands or put our patients in a steam sterilizer and since the chemic disinfectants can not sterilize an infected skin in such concentration as can be used in practice and in such time as is at our disposal it is clear and universally conceded that the crucial point in the sterilizing process of the operator's hands and the patient's field of operation must lie in the mechanical removal of the present and innumerable microorganisms in these situations. This can also be essentially accomplished by razor, nail-cleaner, water, soap, brush and towel, but any absolute surgical operation is hardly within possibility, as the surgical microorganisms not only are met with in the deeper epidermic layers, but also in the different adnexa of the skin. That disinfection which results from a careful mechanical treatment of the skin, has been made fractional by different authors, some putting it at a half, others at two-thirds, while, as is well known, there are those who both on this and the other side of the Atlantic find in the mechanical operation the ideal in surgical sterilization of the epidermis. In my opinion we can not well express in definite fractions the aseptic value of mechanical disinfection, since in the first place individual differences obtain in high degree and since in the second place mechanical disinfection is an art exercised by different operators in extremely varying degrees of efficiency. It is unfortunately not to be denied that those operators who really understand how to wash themselves surgically still are in the minority, which is deplorable, as I am one of the many who have arrived at the conclusion that mechanical disinfection can nearly approach surgical asepsis, if practised intelligently. We should certainly be spared the painful spectacle of seeing a surgeon omit to remove his finger rings and at the same time it is only a reasonable demand that the shirt sleeves are rolled up beyond the elbow. It is unquestionably proper to use a razor on the field of operation, not so much for the sake of the hair as for the skin, whose disinfection is greatly facilitated. The surgeon himself by rights does not shave his arms or hands, which would be a necessity if this process showed a *sine qua non* for the disinfection of the hair. The washing itself must be performed in a routine manner; first a general soaping and scrubbing, thereupon a special ditto of each part. The extensor surface of the arms is reached by flexion and not by extended pronation or supination. Special attention is given the finger ends, the nails and the folds between the fingers. The more changes of

the water (preferably running and sterile), the higher temperature (up to 120 degrees F.), the cleaner the brush (best a stiff one), the purer the soap (boiled, green soap) and the longer time devoted the better is naturally the result. It is certainly proper that we afterward wipe the skin treated in this manner with a sterile towel and when this is done, we have in all essentials removed what practically is all-determining, and we can, as a rule, proceed to any operation whatever with a good conscience and with justified hope for an aseptically good result so far as the operator's hands and the patient's field of operation, treated similarly, is concerned. Yet it is necessary beyond being a good washerwoman to be both an able and experienced operator in order to attain aseptically good results from the mechanical disinfection alone, and as it falls to the lot of comparatively few to become at the same time able and experienced surgeons, it is advisable for those who are not specialists, that they do not only extend the traditional one minute, but that they add something more. It is customary to scrub the skin with strong alcohol, ether or turpentine after the thorough washing with soap. The method is certainly justified, as the above named articles are of recognized value in the removal of grease spots. To be sure, we advance a step further by our energetic scrubbing with one of these agents, followed by drying with a sterile towel. There are even those who consider alcohol omnipotent in the disinfection of the skin, and we can not very well refute such an assertion. However, these strongly fat-dissolving agents make the skin dry and brittle—an unpleasant occurrence for sensitive skin—for which reason many, among them the author, have discontinued the use of both alcohol and ether and preferred to make the remaining microorganisms innocuous by chemic agents, of which more below.

By the mechanical disinfection we aim to the greatest possible extent to dissolve and remove the oily skin covering, rich in bacteria. This fat plays an important rôle in the economy of the skin. It is to keep it pliable and elastic; it is to receive and arrest and thus prevent the innumerable bacteria, which come in contact with it, from causing local or universal trouble. Therefore it appears to me proper to restore to the skin that protective we have endeavored to deprive it of, in the form of a sterile fat, not only for the sake of the skin, but also to cover up and arrest the remaining bacteria and thereby prevent them from infecting the operation wound. The idea is not new, but is for the time being hardly realized beyond examinations and operations on the vagina and the rectum. I believe that this method has quite a future in surgery generally, if we employ a material of the same composition or quality as that which is found upon our skin. Lanolin is the fat which I have tried for this purpose during the past year, and provisionally I have every reason to be satisfied therewith. Lanolin is, as known, a product of sheep's wool; it does not saponify or become rancid, has a remarkable penetrating power and sticks excellently to the skin. Lanolin absorbs water greedily and the commercial article contains about 25 per cent. This is simply called lanolin and forms an almost white, salve-like mass, while the dehydrated lanolin—lanolinum anhydrium—looks like honey and is of the consistency of vaselin. Pure lanolin is without smell or taste. Dehydrated lanolin is simply sterilized by boiling. It boils at a temperature of above 400° F.

—a temperature which instantly destroys all bacterial life. The ordinary lanolin can not be sterilized in this manner, as the contained water will be separated and on boiling cause the lanolin to be thrown to all sides. It must first be dehydrated, which is fairly well accomplished by heating in a steam sterilizer for some time, after which it is set away to be cooled. The water will accumulate below while the dehydrated lanolin will solidify above. When this has taken place, a hole is made through the lanolin and the water is emptied, after which the lanolin is carefully heated up over a weak flame to boiling point; it is now surgically sterile. A convenient mode of keeping sterilized lanolin ready for use is to pour some into a sterilized glass-stoppered or patent-stoppered flask and add to it four or five times the volume of anhydrous ether, which keeps the lanolin dissolved. If a little of this solution is poured on the hands, a few moments suffice to rub it well into the skin; the ether evaporates quickly and the lanolin remains. Another method convenient in military service is to run the lanolin, when melted, into collapsible tubes, such as painters use, sterilized beforehand by boiling. A small amount is pressed out and well rubbed into the skin, after which the excess is removed by a sterile towel and pressing out from under the finger nails.

CHEMIC DISINFECTION.

After having softened up and removed the epidermic dirt mechanically, it is a standing rule to wash or scrub the skin with corrosive sublimate solution to destroy the bacteria which have not been or can not be removed. Theoretically no criticism can be made against this practice; practically I am strongly inclined to believe that the whole is a comedy of errors. It is not denied that corrosive sublimate is chemically the most powerful germicide at our disposal, but Geppert's well-known experiments, which have been corroborated by later investigators (Abbott and others), have long ago proven that it not only requires a 1:1000 solution a long time, even hours, to destroy surgical bacteria, but also that the latter must be exposed on pure culture, conditions which rarely obtain in practical life, not even after the most thorough mechanical disinfection. Corrosive sublimate must form a chemic combination with the protoplasm of the microorganisms in order to unfold its germicidal power, which does not occur when these are imbedded and hidden in fat, albuminous material and dirt. It is an every-day occurrence to see how a sublimate solution rolls off the skin like water on a duck's back, without the least impregnation; the result is in the main the same when the skin is washed beforehand with warm water, soap and brush, or even with alcohol. No name-worthy difference is to be remarked with the addition of tartaric acid to the sublimate. Even if, with an energetic brushing extending over minutes, we succeed in forcing some of it into the skin, this impregnation is always in the first place superficial, and in the second, the time is too short for any germicidal action; thereto is added the wiping or washing off of the excess of sublimate whereby we, for justified fear of toxic action, renounce the antiseptic rôle which these drops could play in the operation by inhibiting the growth of present germs. For these and other reasons I have entirely abandoned sublimate in the disinfection of my hands, while I still recognize its value on

the site of operation when, as is the rule in civil surgery, we can expose this to its continued action for a day or two in weak solution. That the skin in this manner can be impregnated and the bacteria killed or rendered innocuous, I see a proof of in the eczemas which arise and in the cases of poisoning which may be the result of these wet applications; cultures from scrapings of the epidermis are also negative, as a rule.

The English antiseptic, carbolic acid, is by far less germicidal than sublimate, for which reason this agent for the same purpose is used in per cents. where sublimate is used in per milles or fractions thereof. But carbolic acid has the undeniable and great advantage over sublimate, that it penetrates the skin without previous preparation of the latter. Thereupon depends its antiseptic power, and consequently also the danger of poisoning. Carbolic acid will not be able to kill anything in the short time and in the strength which is at our disposal; it has no justification as a germicide, an agent which annihilates the vitality of the microorganisms, but as an antiseptic, an agent which inhibits their growth without destroying their vitality. This last is sufficient for the purposes of the surgeon, since the phagocytes immediately begin their important scavenger work, and generally with decided success when the number of dormant bacteria is small and their virulence moderate. Although sublimate in a concentration of 1:300,000 inhibits the growth of microorganisms, while carbolic acid requires a strength of 1:850 to accomplish the same, the last antiseptic is preferable for the reasons above given.

In the meantime carbolic acid possesses important disadvantages. Many surgeons can not use it, because it causes annoying eczemas or in any event dry and chapped hands and anesthesia. Carbolic acid as an application on the skin, mucous membranes or on wounds is furthermore an exceedingly dangerous agent to the organism, and cases of poisoning have been both numerous and fatal, and often compromising. For these reasons I never could persuade myself to employ this chemical in disinfection of the skin, but have cast about for an agent which has the advantages but not the drawbacks of carbolic acid. Such an agent probably does not exist. I have provisionally availed myself of lysol, which possesses its good qualities in the same or higher degree and its disadvantages in less. Lysol is saponified phenol; it is derived from cresol, a coal tar product of superior antiseptic power to carbolic acid, by the action of nascent soap. It is a good antiseptic in the strength of 1 to 3 per cent. Lysol is viscid, brown and strongly alkaline. It dissolves very readily in water, which carbolic acid does not do; the solution foams like soap-water, penetrates the skin easier than carbolic acid, makes the skin soft and pliable, burns a little and causes after a short time a feeling of numbness. Its toxic properties are not as marked as carbolic acid. It is on the whole eminently qualified for washing the hands and site of operation, whether the skin is broken or not, while continued wet applications have to some extent the disadvantages of carbolic acid with regard to burning and the production of eczema, for which reason I still prefer weak solutions of sublimate for this purpose.

I believe that military surgeons should adopt this practical, inexpensive and good preparation, which is at the same time both a soap and an antiseptic, as the

disinfection of hands and field of operation according to Fürbringer's method (warm water, soap, brush, nail cleaner, alcohol, sublimate and sterile towel) always will be impracticable in actual service.

The disinfection, which I will take the liberty to recommend in military service as well as in civil, where circumstances admit of it, is as follows: Brush the hands intelligently with a clean, stiff brush in a quart of hot water, to which has been added by guess a tablespoonful of lysol; then cleanse the finger nails; cleanse anew the hands with a fresh solution of lysol and another clean brush, dry them with a sterile towel and rub thereafter the hands thoroughly with lanolin from the collapsible tub; remove the excess of lanolin. In the absence of hot water use cold water for a longer time; in the absence of any water simply rub the hands with lanolin, which, under all circumstances, is better than nothing. The field of operation is treated in the same way. It is within the possibility, that it might be of some value to render the lanolin antiseptic with lysol, where we are prevented from using both separately. As is well known the antiseptics certainly lose a good deal of their value by being mixed with fatty substances—considerably less, however, in lanolin. In the meantime I am not so far advanced in my experiments with antiseptic lanolin that I feel justified in expressing myself concerning this for the time being.

THERMIC DISINFECTION.

While cold is not able to destroy microorganisms, but simply inhibits their growth, heat on the contrary is the best germicide. Practical application in surgery finds heat in the form of hot air, boiling water and steam. Hot air is a much more powerful disinfectant than chemicals, but it is considerably inferior to boiling water and steam. Koch and Wolfhügel have found that non-sporebearing bacteria are destroyed in the course of one hour and a half in hot air at a temperature of 212 degrees F., while spores require a temperature of at least 284 degrees F. for three hours for their destruction. To this disproportionately long time dry heat possessed but little penetrative power. It takes a very variable and at any rate a very long time to bring the temperature up to the desired height in the articles to be sterilized, while as a matter of experience it is very difficult, not to say impossible, to obtain a uniform temperature in dry heat sterilizers, for which reason the thermometer is not a safe guide. When to this is added, that the dressings suffer considerably in continued and high temperature, that the instruments rust and lose in temperature and edge, and that these sterilizers are both cumbersome and expensive, it is no exaggeration to maintain that sterilizers for hot air alone only should be of historic interest in surgery. However, there is one important material which seems to be most properly adapted for sterilization by hot air, viz., catgut, which as is known neither stands boiling water nor steam, and whose sterilization by chemical means so often has proved to be unsatisfactory, not to mention the long time required. As catgut, because of its absorbability more and more gains ground *pari passu* with the perfection of its sterilization, both as a suturing and ligating material, and as I have long been of the decided opinion that the surgeon himself shall undertake or in any case control his asepsis, I have devised the sterilizer, which I later will demonstrate, to include also hot air.

so that it can be utilized for catgut, which, so far as I can see, ought to have quite a future in military surgery for the reason that it can be at hand in a very convenient form. Benckisser deserves the credit of having conceived the happy idea of sterilizing catgut by dry heat in double, hermetically sealed envelopes—one within the other. Since microorganisms can not penetrate dry paper, the catgut will remain sterile indefinitely, if the envelopes are kept dry. This is indeed convenient. In this way we can carry sterile catgut in our pockets; when it is to be used, an assistant tears the outer envelope, which is infected on its outer side, while the surgeon himself or his first assistant removes and tears the inner, sterile envelope, which contains the catgut. Benckisser's idea has impressed me so favorably that I long ago adopted it for all the catgut I employ in my surgical practice, but with such modifications that I shall take the liberty to describe my procedure *in extenso*.

The raw catgut, which must be of prime quality in order to retain the necessary strength after the exposure to a prolonged and high temperature, is simply cut without special preparation of the hands into suitable lengths. The original bundle is divided so many times that each individual string measures respectively twenty or forty inches—two convenient lengths for practical use. Each of these strings is wound around two fingers in a coil, which then is wrapped up in wax paper, and since the mercantile article is very thin and easily perforated by the free ends of the coil, the wax paper is doubled, whereupon the whole is placed in a small envelope, which can be hermetically sealed and upon which is marked the length and size. The catgut is placed as nearly as possible in the middle of the envelope, which is now ready for sterilization. When the required amount of envelopes is made up they are arranged in a specially constructed metal box whose bottom is perforated and whose cover is provided with a small funnel to easily admit the thermometer to the interior of the box (see illustration). The envelopes are set up edgewise and must not be packed more tightly than will admit of free space between each one to allow the free circulation of the hot air. According to the thickness of the envelope, which depends upon the size and length of the gut, the box will receive from 150 to 200. The catgut box is now placed in the sterilizer; the pan is filled with cold water; the hood is applied without the cork; a thermometer, which registers up to 400 degrees F., and short enough to be completely hidden inside the apparatus, is slipped in so that the bulb rests upon the upper edge of the envelopes. The sterilizer is now put over the burner. For the sterilization of catgut it is important to employ a burner which can be regulated and which will not soot, since the last interferes with the raising of the temperature. We must use either a good gasolin or a gas burner, preferably with two regulating cocks. We begin with a very small flame, increasing it hour by hour, until the temperature at the end of three or four hours is at the required point (about 284 degrees F.). When this temperature is reached it is continued for at least three consecutive hours, after which the flame is turned off and the catgut box removed after cooling. The whole procedure requires at least six hours, of which three are consumed in the gradual heating up. As the original quantity of water—about one gallon—does not suffice for so many hours' boiling, water must be added time

after time. This takes place without interruption of the sterilization or name-worthy reduction of the temperature, as it is indifferent whether the water poured into the lip be warm or cold.

I have already mentioned that the thermometer must not extend beyond the apparatus. If it does some of the vapor will be condensed on its projecting end and run down along the thermometer to the bulb, which will be to some extent cooled and register falsely. A loop is to be fastened to the upper end of the thermometer to allow of, from time to time, its rising sufficient to read off and control the temperature. It is not difficult at all to keep the proper temperature, so much the more as it is not necessary, not even possible to retain the temperature at exactly 284 degrees F. It suffices that the temperature does not descend below 280 and preferably not above 300, as higher degrees will burn the catgut; still it can stand a short exposure to 320 without being destroyed. It is to be remembered that it takes time for dry heat to communicate its temperature to the envelopes and their contents and that this communication does not keep pace with the gradual rise in the temperature of the hot air. We must bear in mind the little penetrating power of hot air and that paper is a poor conductor of heat, consequently it is wise to continue the sterilization for fully four hours after the thermometer registers 284 degrees, to be sure that the envelopes have had the benefit of this temperature for at least three hours, the time required for the complete destruction of spores of anthrax. When the envelopes are removed after complete sterilization, we will observe that they have changed in color from white to yellow; that they are oily—especially pronounced immediately over the coil—and very slippery. The yellow color is most marked at the lower border of the envelopes; evidently the temperature has been greater at this location. This has also been the case, as is evidenced by a glance at the illustration below. In this apparatus the hot air enters from below; at the wire diaphragm, upon which the catgut box rests, the temperature is, with good flame, 300 to 320 degrees F.; the temperature sinks gradually higher up, so that it is only about 240 degrees in the upper part of the sterilizing chamber, because this is surrounded on all sides by steam at 212 degrees, which consequently lowers the much higher temperature of the hot air. It is only in the lower two or three inches of the sterilizing chamber, that the temperature can be raised to at least 284 degrees; this part is alone suitable for the scientific sterilization of catgut, for which reason the catgut box is made but two inches high and the envelopes a little less to allow for the flange of the cover. The bottom of the box is perforated to admit of the entrance of the hot air. The temperature is taken at the upper border of the envelopes to make sure that the whole envelope is exposed to a temperature of not less than 284 degrees. There is as a rule about 20 degrees difference between the superior and inferior border of the envelopes; therefore, the color is more brown below, and for this reason I take the simple precaution to place the coil in the middle of the envelope to insure against burning and to secure the most possibly uniform temperature. After a few trials of the apparatus and a little experience in packing the envelopes uniformly, it is hardly necessary to observe the thermometer, because we know how wide open to leave the regulating cocks to obtain the desired tempera-

ture; patent gas regulators are superfluous. In order to provide for free circulation of hot air between the individual envelopes, especially at the location of the coils, arrange according to the illustration.

Cultures from catgut sterilized as above have without exception been found surgically sterile. Even the virulent spores of anthrax are destroyed, as is evidenced by the tubes here exhibited, while the pyogenic bacteria have succumbed long before—212 degrees F. for one hour and a half being sufficient, as stated above and verified by numerous cultures of my own. However, bacteriologically sterile catgut is not always achieved. At times colonies of hay bacilli and their spores are encountered. Happily these microorganisms are non-pathogenic and their destruction entails

generally also the destruction of the catgut. If you will kindly open some of these envelopes, which I sterilized a few days ago, you will be surprised to find that the individual strands apparently have lost nothing in strength from the high and continued temperature. Reverdin, who claims the honor of having been the first to suggest dry heat as the safest disinfectant for catgut, is of the opinion that the reason why it so often became brittle in dry heat was owing to its being burnt in its own fat. This is not my experience. At times I do find, it is true, notable

variation in strength, not in the same, but in different boxes of catgut, but this can impossibly be ascribed to the fat, since the temperature has been the same in all. I believe that which Benckisser to my knowledge first called attention to and which Reverdin also in his last book admits is important, that it is the water contained in the catgut which is the determining factor. If the catgut is heated too quickly it will literally be boiled in its own water, and catgut does not stand boiling in water. The heating must be slow and gradual, so that the catgut will be absolutely dried long before the boiling point is reached. This is undoubtedly the secret, and if this is strictly complied with we will invariably find as a result the catgut in prime condition as regards strength. If the catgut in spite of this proves brittle we must not seek the cause in the fat contained, but in the quality of the catgut. I use with great satisfaction imported German catgut, marked 00, 0, 1, 2, 3, etc., and I spare to the poor kangaroo his costly tendon.

Benckisser removes the fat from the catgut with ether; Reverdin employs catgut delivered fat-free from the factory; I, on the contrary, retain the fat and even envelope the catgut in wax-paper in order to add more to it. A part of the grease goes out into the envelope, but a good deal remains in the catgut itself. I do not remove the fat of the gut, because I have found, what any ordinary sound mind could have predicted: 1, that pure fat, heated to a temperature of 284 degrees Fahr., could not diminish the strength of the catgut either more or less than hot air of the same temperature. 2, the most important, that fat containing catgut is a much less favorable culture medium for all pathogenic microorganisms than fat-free; and 3, that fat containing catgut does not soften and become absorbed as quickly as the fat-free. Even surgically sterile catgut is not exempt from occasionally causing sepsis; this sounds paradoxical, but can occur, when sterile catgut is used, under circumstances which do not or can not insure perfect asepsis. An aseptic result demands not only sterile catgut but also, that everything brought in contact therewith be likewise sterile; hands, instruments, solutions, towels and last, but not least, the field of operation. Provided that catgut has not been infected in handling, but that the site of operation, where the catgut is to be used either as suture, ligature or both, is not aseptic, the catgut will form a good culture soil for the bacteria present, upon whose number and virulence the successive resistance of the fat, contained within the catgut, depends, leaving out of consideration the more or less effective phagocytosis, which is equivalent to the degree of vascularity of the tissues and of their integrity, together with the general condition of the patient. In the skin, which as already stated, only with great difficulty, if at all, can be rendered aseptic, sterile catgut therefore will likely produce stitch-abscesses. This applies especially where the skin is poor in blood vessels and under tension. We certainly can evade this complication by adopting Halsted's painless subcutaneous method of suturing, which commends itself as a timely procedure and whereby the bacteria of the skin and its adnexa are avoided. Those surgeons, who do not feel inclined to adopt this mode of suturing and who dread stitch-abscesses must consequently renounce the use of catgut as a skin-suture and reserve this ideal material for buried sutures and for ligatures, provided they, like myself any many others, are fully

convinced of its complete security for both purposes.

Were catgut rendered not only aseptic, but antiseptic, what would then be the result? Should we not expect, that such catgut would be a proper material for skin sutures? The answer has practically been given long ago. Catgut which has been sterilized by means of antiseptics—which is admitted can occur—will become in spite of this a favorable soil for bacteria present as soon as the chemical is absorbed and then sepsis will occur—an old experience! Chemicals have not up to date solved the question of the applicability of catgut in skin sutures.

(To be continued.)

TOXICITY IN HYSTERIA, EPILEPSY AND NEURASTHENIA—RELATIONS AND TREATMENT.

BY ALBERT E. STERNE, A.B., M.D.

PROFESSOR OF NERVOUS DISEASES AND CLINICAL MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS; CONSULTING NEUROLOGIST TO CITY HOSPITAL; PATHOLOGIST TO CITY DISPENSARY, ETC.
INDIANAPOLIS, IND.

Of the many causes of hysteria, epilepsy and neurasthenia one of the most frequent and important seems to me to be toxicity in some form. Yet it has heretofore received little attention as an etiologic factor in the induction of these affections, all of which may be regarded as diatheses of more or less profound nature. To the toxic element in these diseases I wish especially to draw your notice. The term toxicity should, however, be used in its broadest sense, namely, functional cellular perversion, causing or being caused by abnormal chemic reactions.

The ordinary forms of hysteria are certainly functional. I do not believe we shall ever discover pathologic alterations in the central nervous system, even of minute degree, upon which we may base those manifestations which we call hysteric. By this, however, we do not mean to assert that hysteria may not depend directly upon an organic lesion situated outside of the nervous system. It is the expression in many instances of perverted chemic action or of abnormal cellular activity within the nervous system itself. In other cases the disturbed function of other organs exerts an immediate, yet secondary influence upon the nerve cells, and induces very severe forms of hysteria. So, for instance, we find those suffering from intestinal, biliary and renal troubles, and from thyroid enlargements, presenting grave cases of this disease. We have in these instances, and they form a large proportion of the entire number, a state of veritable cellular intoxication. It matters not what the nature of the active poison may be, the ultimate change is similar and is probably always cellular and, moreover, temporarily toxic. It is not necessary to suppose that the change must be structural; it suffices to consider it chemic. How else can we explain the physiologic action of certain drugs upon the nervous system? And many drugs bring about a condition closely allied to the hysteric. That we do not know the exact manner of this action is due rather to our deficient knowledge of nerve chemistry, than to any undiscovered structural pathologic alterations. Other cases originate from a third cause, shock, in a variety of forms. Here, again, we may assume that cellular perversion, dependent upon shock or injury, lies at the bottom of the hysteric state.

There are undoubtedly other causes of true hys-

teria, spurious forms simulating the real, which are born wholly of a morbid desire for sympathy and condolence. If we seek far enough we usually detect conditions in nearly all cases which point to some form of cellular malnutrition and abnormal nerve-cell activity. It is this point which I especially wish to emphasize, for only too often the physician fails in his treatment of these cases because he contents himself with the meager diagnosis of hysteria—and never attempts to discover any basis for his diagnosis.

In one direction this search for the causation of hysteria has led to extremes. I refer particularly to those who have taught that the genital organs of women are the main causes of hysteria and have performed grave operations to relieve the reflex affection, with very little benefit to their patients. Where uterus or ovaries are diseased they should, if necessary, be removed and doubtless when these pathologic organs have been taken from the system an improvement in the general nervous state often results. But the operation should be done because the organs are diseased, not because the sufferer may have concomitant hysteria. When these or any other organs are sound I doubt if their removal is ever justifiable.

It must not be inferred that there is not a reflex origin of certain nervous conditions. On the contrary, we meet with such an etiology very often, though perhaps not so frequently as some enthusiasts declare. Any diseased organ may become a source of reflex nerve irritation. But the genital organs are probably no more to be blamed than other organs, for instance, the stomach. We must not lose sight of the fact that the vast majority of women have some more or less severe genital trouble. This they may owe to their husbands or to the alleged advantages of civilization. It should, therefore, not be surprising to find that most of those afflicted with hysteria should be similarly affected. Men often suffer from the disease in its severest form. In fact, the masculine hysteric is usually more intractable than the feminine. Some of the worst cases I have seen have occurred in men. These facts are important and a recollection of them will sometimes materially alter seemingly grave situations. I have seen cases of absolute paralysis and mutism in male hysterics, where a diagnosis of organic lesion had been made. Hysteria is wont to be more stable in nature in masculine than in feminine subjects: it is one of the most characteristic features of the affection. The symptoms in women and girls often vary with considerable rapidity, whereas the opposite is common in men and boys. This peculiarity goes far to explain the symptomatology of the traumatic neuroses, so much more frequently met with in a stable form in men than in women.

Of the ordinary symptoms convulsions alone deserve special mention, and these we shall discuss in connection with those occurring in epilepsy. There is an intermediate state—hystero-epilepsy—which shows features of both affections, but this state also we may pass over without dwelling upon it particularly.

Epilepsy, like hysteria, may be regarded as a diathesis, but of a more profound nature. Here, again, I should make distinctions of etiology similar to those of hysteria, but with this distinction, that in true epilepsy we find pathologic changes in the structure of the central nervous system. Aside from cases of so-

called Jacksonian epilepsy, where we have gross cortical, subcortical or extra-cerebral lesions, the changes ordinarily found are of a vascular nature. Heretofore no constant histologic cellular alterations have been found. Numerous minute hemorrhages scattered throughout the brain substance, notably in the cortical gray matter, have been almost invariably seen, but these should, I think, be regarded as the result of the changes in the walls of the blood-vessels. As I have recently pointed out¹ the walls of these structures are usually thickened and therefore less elastic than normal and very liable to rupture. The minute apoplexies should not be looked upon as the cause of the epileptic attacks. The changes in the vascular walls are produced by the action of some toxic agent which at the same time acts chemically upon the ganglionic cells of the cortex and causes the malady we term epilepsy. In many instances, perhaps in the majority of cases, we certainly have to deal with the effects of auto-intoxication. The periodic character of the disease is to me no insignificant proof of this view. Over a year ago I stated that I regarded many diseases of the nervous system, among them epilepsy, as of toxic origin. Recent researches support this opinion. The action of xanthin and paraxanthin, leucomaines of the uric acid group, when these substances are present in the blood in abnormal, though very minute quantities, lends distinct worth to the toxic theory of the etiology of true epilepsy. (Rachford, *New York Medical Record*.) The sequence of symptoms in the disease differs materially in various cases, though it occurs with peculiar constancy in individual instances. The seizures of any one given person are very much alike, from the aura or prodroma to the end of the entire attack. The intensity of the different paroxysms may vary considerably, from the mildest epileptiform warning to fatal coma. The attacks themselves may sometimes closely resemble severe hysteric seizures. There is, however, one fundamental difference between the convulsions of hysteria and epilepsy. The former are probably never dangerous and the patients seldom pass into an unconscious state; the latter may be very dangerous and even fatal, and loss of consciousness usually occurs. An hysteric patient never hurts herself and ordinarily falls in some convenient place. An epileptic, on the other hand, readily comes to grief.

The character of the muscular spasms deserves a concise consideration. As a rule those occurring in essential epilepsy follow in certain order in the different attacks of a given individual. This is especially true in cases of Jacksonian or cortical epilepsy, notably where the lesion is situated over or in the vicinity of the fissure of Rolando. The centers for the various muscular movements lie in this region in known positions, those for the leg being uppermost near the vortex. Next to these are the centers for the arm, the face and the tongue in the order named. If, therefore, convulsions occur they must follow in exact physiologic sequence. If the muscular twitchings begin in the leg, those of the arms must take place before the lower half of the face on the same side is affected. The spasms can not under such circumstances spare the arm or extend from the leg immediately to the face. The contractions of the tongue, if they be present, can not usually be seen, as the mouth is nearly always tightly closed. Such

an exact sequence of the convulsive movements in hysteria seldom occurs. It will be noticed, therefore, that though the two diseases have some striking resemblances they really differ materially, and it will not usually prove difficult to separate the one from the other.

Fortunately neurasthenia is not often complicated by concurrent epilepsy or even by hysteria. This class of cases was long included among the hysteric affections. From these, however, they differ considerably, notably in that the latter are very much more frequent in the female sex, whereas neurasthenia is preëminently a disease of the male. Men who have led active business lives, who have consumed their stock of nervous and vital force rapidly, are commonly candidates for this trouble. Again others who have unceasingly applied themselves to mental overwork are attacked. Others again who have been long exposed to the influence of certain drugs, for example lead, mercury and nicotin, become afflicted. It is an important fact, however, that the majority of these patients are at the same time suffering from such chronic organic lesions as notoriously cause the formation of noxious metabolic substances, namely stomach, intestinal, liver and kidney troubles. In this affection once more we find ultimately cellular functional perversion brought on by a variety of factors. Yet the condition differs much from hysteria and epilepsy. In neurasthenia we have essentially a state of perverted cellular vitality, not only of the nervous system, but frequently also of the entire body. Energies long misapplied have finally induced a condition in which the vital forces themselves become misapplied. Neurasthenia resembles in many ways hypochondria, but the two are distinct. The latter is a functionally perverted state due to individual inherent characteristics; the former is a like condition of physiologic over-exertion in certain directions. The ultimate result may, however, be very similar.

I distinguish three degrees of neurasthenia, namely, 1, light grades or nervous weakness, 2, middle grades or nervous prostration, and 3, severe grades or nervous exhaustion. This distinction is purely arbitrary, but very convenient both for prognostic and therapeutic purposes. Under all three classes I again distinguish *a*, simple sexual neurasthenia, and *b*, spinal, respectively cerebro-spinal neurasthenia, of which the sexual weakness may be an essential part. Sexual neurasthenia is virtually an affection among men, and commonly of young men. Yet it is not necessarily the result of a vicious life. Under this class I do not include those cases which might be termed organic, inasmuch as they depend upon some peripheral lesion, usually of gonorrheal origin. Simple sexual neurasthenia is a purely psychic condition of functional inability to perform certain relations. It is usually the result of a failure or repeated failures in attempting to fulfill these relations. Upon this experience conviction of this inability to properly play the rôle of man becomes so firmly established that ultimately an actual, yet purely psychic, weakness in this respect develops. This condition may and often does remain stationary, but it may become intensified and lead to the severer form of spinal neurasthenia. On the other hand, sexual weakness usually forms an essential characteristic of all severer forms of spinal and cerebral neurasthenia. These severer forms often appeal to us as extremely serious conditions and, though lacking a fundamental nervous basis, they are

¹ JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, July 20, 1895.

in reality grave, and necessitate the utmost care and skill in their management. As in hysteria and epilepsy, so here also, we need not speak of the manifestations of the various forms of neurasthenia, but rather proceed to discuss the treatment of these three conditions in a concise manner.

Of epilepsy I need say very little. In every case a possible toxic origin should be kept in mind and sought for. If found and successfully counteracted rapid amelioration in the patient's condition should and does result. My best experiences have certainly been in this direction. Otherwise the old routine treatment with the bromids, eventually combined with the iodids, or with borax, offers the surest means of rendering the attacks less frequent and severe. Complete cures under this therapy are certainly rare. Wherever a positive diagnosis of local cerebral trouble can be made, or even where reasonable suspicion of an organic focal lesion can be entertained, surgical methods are justifiable and should be practiced. It should be remembered that epilepsy is not infrequently of reflex nature, either from the eyes, nose or other organs, and abnormalities of these parts should be corrected. Scars or an adherent prepuce also sometimes induce epileptiform paroxysms, and where this is the case surgical methods are again in place. Unfortunately enthusiasts have brought the reflexes into disfavor.

The exact lines to be pursued in treating hysteria and neurasthenia depend largely upon individual cases and the conditions of life under which these cases exist. It is probably safe to adhere, if possible, to the rule, that change of scene and environment are beneficial to these two conditions. The complete loss of vital forces in many cases renders it often impossible to follow out this precept, until a considerable improvement has been attained. Whenever it can be done, however, an abrupt change in the habits of existence, a journey and especially a sea voyage for neurasthenics should be advised. By surrounding those afflicted by other persons and things and thereby diverting the remaining energies into other channels of thought and action much good may result. High mountain altitudes are beneficial in some cases, in others directly injurious. Ordinarily the sea coast is preferable as a place of sojourn.

Special attention should be given to the conservation of the vital forces still surviving, and the general state of mind and body tonus raised. By suggestive therapy excellent results may be achieved. If properly conducted and patiently carried out this method will often bring about an ultimate cure. It may be well to warn that this suggestive therapy is by no means identical with hypnotism. As a diagnostic aid hypnotism is often useful and may be conscientiously employed. As a therapeutic agent it may, and I think, usually does prove injurious. It has been of great value to me in individual cases, but my own experience, and that of many others, has not been of a character to warrant its continual and irrespective use in the treatment of any class of diseases. Suggestion in the waking state is equally efficacious, always possible and never harmful. It has been contended that it is difficult to hypnotize hysteric and nervous persons, but this is an error. As long as the attention can be concentrated these persons pass into the hypnotic state readily enough, with the ultimate result of further weakening an already shattered nervous vitality. It is therefore not untimely to pro-

test against an indiscriminate use of this certainly powerful influence.

Naturally, whenever we suspect any etiologic factor as a cause of the nervous derangement we should seek to eradicate this factor. By so doing we strike at the root of the evil. In this connection it may be well to draw your notice once again to that which I have said concerning the possibility of auto-intoxication as productive of hysteria, epilepsy and neurasthenia. I have frequently found that persons, notably girls and young women, suffering from severe hysteric manifestations, were afflicted with chronic intestinal and renal disorders; they were essentially chlorotic and jaundiced, and very often were subjects of deranged thyroidal activity. By counteracting the malignant influence alone we may sometimes effect a cure. In addition to the above, and a proper use of medicinal remedies, a judicious bathing and open-air regimen ought to be carried out. My rule in regard to baths, both sponge and full, is to reduce gradually their temperature, but always to avoid the slightest degree of shock. A rational understanding of the effect of cold water is absolutely essential to the physician. Otherwise only poor results will attend his best efforts.

Only two other methods of treatment or, better said, parts of the general treatment need be mentioned, *i.e.*, electricity and the so-called rest cure. The electricity can be used in all of its forms. In my hands general faradization and the static current have been productive of the best results. Too strong currents should never be employed. In the severer forms of hysteria and neurasthenia, the rigid "rest cure" brings the speediest and surest relief. To be successful this should be absolutely carried out in all details, and should be extended over several weeks, and never attempted at the home of the patient. By isolating these cases completely from the other members of the family, by calling to our aid general faradic massage, by husbanding every atom of vital energy and by judicious feeding, even desperate cases improve rapidly and finally recover entirely. But, to repeat, it is absolutely essential that not one iota of nerve force be misspent nor a single portion of the remaining bodily strength be wasted.

CRITICISM OF THE ANTITOXIN TREATMENT FROM A DIFFERENT STANDPOINT.

BY CARL STRUEH, M.D.

CHICAGO.

The enthusiasm for the antitoxin treatment has at the present time become so common that one can hardly dare to give a pessimistic opinion if he does not want to run the risk of being called heretic or unscientific. Still I would like to explain in a few words the standpoint which I take as to the antitoxin treatment.

The statistics show the undeniable fact that since the introduction of the serum-therapy the mortality in diphtheria has decreased to about one-half of its former figure. Yet I think it wrong to ascribe this decrease in the mortality exclusively to the antitoxin treatment, but I take it for a very important causal factor that the serum-therapy, though absolutely not harmless, is less harmful than the drug treatment formerly used. The proof for this assertion is given us by those cases in which we apply antitoxin for

mere prophylactic purposes in healthy persons. The less severe disturbances which the antitoxin causes in our system escape our perception. Still we can say that visible changes in the subjective and objective condition of the person in the majority of cases do not set in; that, in other words, the condition of health of the person concerned is about the same after as before the injection of antitoxin.

Now we may give to a healthy child such drugs as calomel, potass. chlorate, etc., which we used under the old treatment, also a part of those drugs, as chlorid of iron, sublimate and the like, which we used for local application and which are also partly swallowed and absorbed into the child's system, and see if these drugs will produce as little constitutional disturbance as the antitoxin does. If this is not the case, if they are able to make the healthy child sick, is it not plausible then that they must have a more harmful effect on a child that is already diseased and who needs all its vital power to overcome the disease? Can we doubt that many a case that might have been cured otherwise must succumb to the twofold demand made by the overcoming of the disease and the elimination of the drugs the antibacillary and antitoxic effects of which are merely illusory; that, in other words, the mortality must be greater under the use of these drugs than without them?

I call attention to typhoid fever. At the time when we treated this disease with chemic antipyretics and internal antiseptics the mortality was 15 to 20 per cent. Had we been able to exchange this treatment for a serum-therapy, I am sure the mortality would have decreased to one-half also. By Brandt's method of hydiatic treatment it has decreased to less than 5 per cent, and this percentage will never be beaten by any other treatment, by no serum-therapy either. For typhoid the antitoxin treatment comes too late, and it would also have come too late for diphtheria, if we had exchanged the drug treatment directly for a hydiatic one.

What do we intend to do with hydrotherapy in typhoid? We do not expect it to have any influence on the process in the intestines, but we use it as a natural antipyretic and a tonic for the *vis medicatrix naturee*, which alone can cure any pathologic disturbance in our body. Whether we have to deal with the typhoid bacillus, the diphtheria bacillus, or as the case may be, the pneumococcus; whether the lesion exists in the colon, the pharynx, or as the case may be, the lungs, is in my opinion entirely equal. Typhoid is so far the only disease in which we apply a physiologic treatment almost universally and with the best results. And it is inexplicable why the favorable therapeutic experience which we have gained in typhoid is so slowly extended to other diseases. Lately we have commenced to treat pneumonia with hydrotherapy, but why do we not use this treatment in every acute disease whatever, as in diphtheria? If I defend the hydiatic treatment of diphtheria, it is not only for theoretical reasons, but for practical experience and I do not doubt that a controlling treatment of diphtheria by hydropathy on the one, and by antitoxin on the other side, would certainly be in favor of the former. By the way, I want to call to mind the better convalescence, the *restitutio ad integrum* which we almost always find after the hydiatic treatment.

I need not say, that as long as the majority of the physicians neglect the use of hydro-therapy, the

antitoxin treatment will hold the field for a long time, and as to the practical results we can be satisfied for the present, for we have made a good change anyhow, if we remember the old drug treatment (drug poisoning). Still we can be sure that the antitoxin treatment will some time disappear, and the physiologic treatment, the therapy of the future, will be applied by all physicians. Then we will treat diphtheria in a natural way, as we do typhoid now, and the mortality will be nearly as low as that we now have in typhoid; that means it will be considerably lower than it is under the antitoxin treatment.

The followers of serum-therapy maintain that on the application of antitoxin the whole course of the disease changes, that the temperature decreases, the general condition improves, the appetite gets better, the swelling of the glands diminishes, the membranes disappear in a comparatively short time, etc. Why, to decide this point, we have to wait for some more impartial opinions. In the first enthusiasm for a new treatment we are apt to see everything in a more brilliant light than we do after a thorough investigation. We have had this experience a thousand times with new drugs.

There is nothing so injurious to an impartial opinion as the fact that we are always apt to take the *post hoc* for the *propter hoc*. Every physician knows that there are a great many of cases which change for the better quite unexpectedly, and I am sure that this fact has a great deal to do with many a brilliant result of antitoxin treatment. An illustration of this opinion I lately received from a brother physician, an enthusiastic believer in serum-therapy. His 6-year-old boy became sick suddenly with high fever, swelling of the maxillary glands, difficulty in swallowing and thick coating of the tonsils. The doctor obtained some antitoxin late in the evening, but postponed the injection of it until the next morning, when it was no longer necessary, the boy being entirely well. The fever was gone, the maxillary glands were painless and had greatly decreased, and the membranes were almost gone. This case would have been taken as a convincing proof of the efficiency of the antitoxin, if it had been injected. Similar cases certainly are in the mind of every physician.

A fact that we also must not overlook, is that, as the antitoxin is said to manifest its main power in the beginning of the disease, there is many a simple inflammation of the pharynx taken for diphtheria and supposed to have been cut short as such. It is absolutely necessary that we form our opinion of the value of the antitoxin only from such cases as are diagnosed as diphtheria from a bacteriologic examination, which has not been the general custom so far. I do not know among the physicians I am acquainted with and who are enthusiastic followers of the serum-therapy, a single one who makes a bacteriologic examination in every case and with whom such an examination is not an exception. And I am certain almost every physician must admit the same of himself and his friends. So we can say that the great majority of those cases to which the present fame of antitoxin treatment is due, are such in which a bacteriologic examination has not been made.

But how can we swear to the efficiency of a remedy for diphtheria, if we do not know in every single case whether we have to deal with a case of diphtheria or with a simple catarrhal inflammation? We can not rely merely upon the clinical diagnosis, for

it is, for instance, almost impossible to diagnose a case of diphtheria in its beginning, at a time when the antitoxin is said to be especially efficient. That even advanced cases do not necessarily furnish the clinical symptoms, we see in membranous croup and in those cases in which a diphtheritic paralysis (for instance, of accommodation) occurs, and in which the patient hardly showed any symptoms indicating diphtheria.

The followers of the antitoxin treatment further say that since the introduction of this therapy, the mortality in children who were operated upon for croup has decreased. Even by this fact we must not be filled with enthusiasm too quickly. We know that most of the children affected with croup do not offer severe, but mild diphtheria, and that the dangerous character of croup merely consists of the localization of the membrane, the mechanical occlusion of the glottis. Most of these children are cheerful, have a good appetite, very little fever, only slightly swollen glands, almost no symptoms from the throat, and hardly offer the appearance of a sick child until the mechanical occlusion of the glottis and suffocation set in. If in such a case we provide the child with sufficient air, as we do by tracheotomy, and beside treat the child by a comparatively harmless method, as we do by the antitoxin treatment, it is not surprising that the results will be better than they were at the time when we used to injure the vital power of the child by drugs and when we exposed the child to vapor saturated with chemicals that, though not powerful enough to kill the bacillus, yet were strong enough to have a poisonous effect on the system and which prevented a sufficient supply of oxygen, so immensely important to the almost suffocated child.

As to those injections of antitoxin which are made for prophylactic purposes, we must admit that it is not the rule that from a child being sick with diphtheria the majority of the family becomes infected, at least this is not my experience. If we, therefore, apply antitoxin to every member of a family in which there is a case of diphtheria, we can wager ten to one, of course, that the result will be in favor of the antitoxin.

Whether my opinion which I have given in the foregoing treatise is wrong, or that of the followers of the serum-therapy is right, can not be decided upon, unless we use a little more logic in the investigation of the subject. The followers of the antitoxin treatment declare that it is necessary, in order to get those good results, not to combine any drug treatment, at least not to the extent as formerly used, with the application of antitoxin, and right there, it seems to me, is the root of the whole matter. I do not call it logical to ascribe the decrease in the mortality exclusively to the antitoxin treatment and not pay any attention to the possibility that the exclusion of the drug treatment might have something to do with it. This point ought to be investigated first, for we can not deny the fact that the animal serum is more related to us and less harmful to our system than the chemicals are, and it is logical that the exclusion of the greater evil must have a favorable effect on the mortality.

We know or assume that under the drug treatment also antitoxin was formed in the blood serum of the sick child. If we now would continue this drug treatment and increase the amount of antitoxin in the child's blood, by injecting animal antitoxin, and the mortality would decrease, then we could say that

this decrease is merely due to the antitoxin injected, and nobody could deny this fact. If, however, the drugs interfere with the antitoxin, then we ought to find out first, by excluding the drugs, what mortality there would be if the system, in its fight against the diphtheria poison, had to rely exclusively upon the antitoxin that is formed in the diseased body. Only if we know this percentage of mortality, we can form a correct opinion of the animal antitoxin which we inject into the child. But as we might not like to treat a case of diphtheria by an indifferent treatment, we could easily follow the former way of investigation, and ascertain the mortality which we would have under a combined drug and antitoxin treatment. To exclude the more harmful drugs and substitute the less harmful antitoxin and to ascribe the favorable change in the mortality exclusively to the latter, is a logic that would not be admitted in any other science.

WHITHER ARE WE DRIFTING? INDICATIONS OF A DEGENERATE MATERIA MEDICA.

Read at the forty-fifth Annual Meeting of the Medical Society of the State of Pennsylvania, at Chambersburg, Pa., May 23, 1895.

BY H. A. ARNOLD, M.D.

ARDMORE, PA.

Medieval and ancient history tell us that in those periods of the world's history the practitioner of medicine covered up a vast amount of ignorance under the veil of secrecy and mysticism, in order that he might awe the superstitious and satisfy the incredulous. In those ages the alchemist sought the hidden things of nature, either from love of science or a desire to enrich himself by discovering a means of producing the precious metal. Those ages were followed by one of enlightenment, when rational medicine supplanted mysticism and the nobility of scientific attainment was wedded to philanthropic purposes. Physician, surgeon and chemist worked hand in hand, and surgery, *materia medica* and pharmacopoeia teemed with the products of advanced thought, freely and voluntarily disseminated with no motive save the good of mankind in general, and the advancement of medical science in particular.

In these days practitioners of medicine were for the most part dignified, courteous gentlemen, whose intellectual attainments and excellent judgment awarded them a high place in the esteem of the community, seldom equaled by the clergy, and never by the legal profession. There are living illustrations of the truthfulness of this statement in the persons of some who are still identified with this society though past the three score and ten, or four score years allotted to man; and have we not been impressed with the accuracy of the statement when brought in contact with them?

Time effects many changes, and chemist and medical man have shared in the process of transformation. The product of the laboratory now receives an euphonious designation, is turned over to a number of experimenters, endorsed to order by them with undue haste, whereupon the "Chemical Company," burning with desire to confer manifold blessings upon suffering humanity, issues a very attractive pamphlet which glows with candor on one page and ambiguously obscure upon another, parades the names and string of titles of its stock list of product endorsers, and generously offers, post or express prepaid, samples as a bid for further endorsement. At

the same time they carefully refrain from revealing either the exact composition or method of production.

Take up almost any of the numerous "regular" medical journals and page after page is given up to the conspicuous notice of "antis" and "ines," until one turns away in disgust and wonders where the end will be. I have just opened a copy of a new claimant for a place in the field of medical literature on the ostensible grounds that it is "a condensed summary of the medical literature of the world," only to find that this four page paper has given up one entire page to a most brazen fraud.

The wholesale production of "favorite formulæ," "coal tar derivatives," "animal extracts," etc., has not resulted from honest beneficent motives, but rather in every instance are they the articles of commerce which are expected to enrich their producers, if only they can be extensively advertised with the proper endorsements.

There is one other very objectionable feature about this system of medicine making and advertising, and that is the means made use of to insure the success of the business venture. Short-sighted men are lured, weak men are cajoled and seekers after notoriety need no coaxing to endorse statements, verify results, praise merits and prognosticate a glorious future for the latest wonderful product, all of which is speedily brought to the notice of professional men, who are supposed to ever stand in an expectant attitude, waiting for a new Moses to lead them out of the wilderness of difficulty.

After due notice in the public press, with wise statements as to its mysterious nature, a curious public soon makes its acquaintance, and once in the possession of druggist and public, the manufacturer boldly advertises in street cars, pseudo-medical journals, daily papers, etc., taking care to state that it has received the endorsement of all eminent physicians and is used by the profession in general. I sometimes wonder how an honest physician must feel when he sees his name used to further the business of the A. B., X. Y. Z., or some other "Chemical Company," who having used the profession to introduce their wares to the public, have the unmitigated gall to continue to solicit medical recognition for their most ethical (?) product.

We used to speak of the "gullible public," and comment on the avidity with which they seized hold of much lauded proprietary medicines. Are we not in danger of falling into the same pit, and will not the shoe pinch when the world opens its eyes and sees the *gullible practitioner*, who has fallen from his high estate, and is only a salesman and distributor of proprietary articles and compounds made after formulæ either only partially revealed, or if followed would result in an entirely different product? Faith is commendable; yet, "Oh, ye of little faith" certainly does not apply to the medical profession of to-day. When we follow after strange gods we merit and receive disapproval and rebuke.

Realizing the fact that the study of *materia medica* has been made entirely unnecessary by reason of the enterprising spirit of the unselfish medicine makers, as well as by their profuse distribution of reliable information for the benefit of a profession which apparently is no longer capable of doing its own thinking, I feel almost inclined, in the interest of overworked medical students, to offer an expression of opinion something like the following:

Resolved, That it is the sentiment of this body that, inasmuch as the various manufacturers of medicine and medical compounds have assumed the role of experimentalists, and do generously supply the entire profession with literature voluminously describing each advance, as well as free samples for trial:

We do now suggest to the various medical colleges within this commonwealth that the time now occupied by students in acquiring a knowledge of drugs so soon to become obsolete by reason of the rapid progress in drug making, could be better employed in considering matters of etiquette, society manners and other means of enabling them to earn a genteel living by introducing to the public the valuable compounds brought to their notice by mail and through the columns of the medical journals.

Time does not admit of the elaboration of this subject in a paper limited to ten minutes, hence many phases of the matter can not even receive mention, nor is this the first time the subject has been presented to the State Society, and I hope it will continue to engage your attention until radical measures are resorted to, and this noble profession is wrested from the gigantic octopus that is rapidly enveloping it in its deadly grasp.

I well know that the way of the reformer is hard, and that he is cannonaded during his lifetime, even though he be canonized after death; yet in my obscurity I have no fear of the one, nor will my feeble efforts lead to the other.

Martin Martens, the author of that most enjoyable book, "God's Fool," says, "there was a man once, a satirist and he died. His friends gathered around him and they said indignantly, 'This man treated the whole round world as a football, and he kicked it at every opportunity.' The dead man opened one eye, 'But always toward the goal,' he said."

I sincerely hope sarcasm so imperfectly concealed and so defectively worded, may be forgiven when you fully understand the spirit of charity that prompts it, and the desire for advancement of all professional interests which actuates its author.

COMPLICATIONS IN CATARACT ARISING FROM DIABETES, ALBUMINURIA, LITHEMIA, ETC.

Read before the Mississippi Valley Medical Association, at Detroit, Mich., Sept. 5, 1895.

BY J. O. STILLSON, A.M., M.D.

INDIANAPOLIS, IND.

Whether there exists a positive relation between the development of senile cataract, and the presence of nephritic diseases such as albuminuria, diabetes, etc., seems to have as yet never been wholly proved to the general satisfaction of the profession at large. And yet, that there is at present, and, in fact, always has been an inclination to the belief that there is some such relation, if not positively of an etiologic character, at least of sufficient importance to seriously modify and complicate our therapeutics, there is probably remaining at present very little doubt. The well-known experiment of injecting sugar into the circulation of the frog, thereby causing the opacity of the crystalline lens which clears up again, slowly, when the animal is left immersed in water, may now be classed as one of the old-time experiments in physiology. This interesting phenomenon simply proved that when there was an excess of sugar in the frog's circulation, cataract developed; and inasmuch as the functional power of the frog's kidneys, compared with that of the skin is almost, one might say, trifling, we readily see why that, when the emunctories of the

skin are brought into active exercise by the immersing of the animal in water, the elimination from its skin is great enough, comparatively speaking, to produce a thousand-fold effect in liberating any deleterious substance from the circulation. However, this does not prove why the lens becomes opaque and how it clears itself, again resuming its former transparency. Our knowledge of the whole subject is yet so meager we are forced to admit that many factors in the problem remain yet to be worked out before a definite conclusion can be arrived at in reference to this important question.

Analogous to the phenomenon in the frog, we have the well-known condition in the human species called diabetic cataract. The writer well remembers among the earlier lessons which he received in ophthalmology, how he was taught to regard with suspicion, the presence of a cataract in a person of middle age, or early adult life, who showed the presence of sugar in the urine, and where no traumatic history could be made out to explain the development of cataract. These cases were always to be handled with gloves. The prognosis was never flattering; in fact, they were regarded as unfavorable cases to treat, because as a rule they are liable to have retinitis present, which is unfavorable to an operation, or choroiditis for the same reason, and consequently the risk of post-operative iritis becomes greatly increased; added to the fact that such a lens is far removed from the physiologic condition of simple opacity, if senility can be called physiologic, and it has taken upon itself the metamorphosis of catalytic degenerescence, not far from putrescence; so that the sepsis after such operations from auto-infection is not an impossibility by any means.

If man were plunged into the ocean, or if the eliminating power of his kidneys were augmented a thousand fold, still his diabetic cataract would never clear up, like the sugar cataract of the frog. Why? Because his condition is certainly now no longer a physiologic one. He has long since passed into the domain of pathologic degeneration. All the fibers and cells of his lens have virtually become broken down and separated from each other and the general circulation of the eye, and there encapsulated as it were, they remain as a foreign material, wholly offensive to the circulation.

It is not the purpose of this paper to prove or to disprove anything. It is easy to set up a theory of straw to be riddled with the bullets of adverse criticism; nor can we always depend upon statistics to come to our relief, when a proposition in medicine needs to be proved. There are always, however, certain fundamental facts, which crop out in the clinical study of every case which we can not ignore, however poorly we may explain. Whether arterio-sclerosis and atheroma start out as purely physiologic conditions, to be afterward changed into pathologic states, or whether the prior degeneration of some vital organ like the kidney or liver is necessary to bring about atheroma as a result, is probably easier answered than the query which underlies this paper. This, however, we do know, that whenever atheroma does exist in conjunction with such diseases, as nephritis, diabetes, albuminuria, etc., the senile changes which indicate the general breaking down of the system follow each other in more rapid succession than where organic diseases of the kidney or liver do not exist. Hence it is that a delicate and sensitive

organ like the eye, would be less likely to escape. We therefore are not surprised at the appearance of an albuminous or serous retinitis, as one of the earlier, and sometimes even prodromatic indications of Bright's disease. It does not seem to the writer that we ought to be surprised when find as we do in many cases of cataract, not specially diabetic, the unmistakable evidences of renal disturbance; the presence of a certain quantity of albumin, and oftentimes, in specially nervous individuals, an increase in urea and more or less evidence of sugar in the urine.

L. Webster Fox (*Vide Ophthalmic Record*, June, 1894) says: "Whether an albuminuria causes cataract may be a matter of doubt, but one is struck with the frequent coincidence of albuminuria in cataractous patients. In order to explain this fact in cases of senile cataract, Michel says that it is essential to consider that cataract and albuminuria are the results of alterations produced simultaneously in the eyes and in the kidneys from the same general cause, arterio-sclerosis. This theory recalls, to a certain point, that of Sutton who considered that interstitial nephritis and hypertrophy of the left ventricle are both caused by an alteration of the vascular walls, arterio-fibrosis. Berger, Becker and the greater number of those who have made a special study of this question do not believe in the relation claimed by Deutschmann between cataract and nephritis."

Quoting from Risley, in his admirable remarks before the State Society of Pennsylvania, May, 1895: "The great liability of gouty and rheumatic persons to transient vaso-motor derangements, to persistent and recurring inflammation of the mucous membranes and fibrous tissues, and to changes in the vascular walls is too well known to need comment in this presence. When it is remembered that these structures are so uniformly represented, in most highly organized forms, in the eye and its appendages, it is not to be supposed that this important organ would escape the influence of the uric acid diathesis. Indeed clinical experience furnishes ample demonstration of its extreme liability to participation in this class of affections dependent upon this malady of nutrition. By way of illustration it is needful only to mention the fact that in the etiology of iritis, this diathesis stands second only to syphilis in its number of victims, while in stubbornness to treatment and tendency to recur it stands first." And again: "The high arterial tension, the hypertrophied left ventricle, the chronic nephritis, and contracted kidney, the rigid arterial wall becoming atheromatous, apoplexies, angina, etc., present a picture of serious diseases which unfortunately we are only too frequently called upon to witness. It can not be supposed that the ocular blood vessels would escape the disaster which has fallen so heavily upon the general blood vessel system. Indeed, when we are reminded that the nutrient coat of the eye—the choroid—is a meshwork of blood vessels ramifying through a loose connective tissue stroma, we are prepared to expect the clinical picture which is so frequently presented for study. Since the dioptric system of the eye enables the surgeon to study the intra-ocular tissues under an enlargement of about fourteen diameters, it affords a unique and favorable opportunity to study the pathologic changes going on in living structures. It is under these conditions he is permitted to observe the innumerable small apoplexies in hemorrhagic

retinitis, and in the latter stages of nephritis (*morbus Brightii*); in perivasculitis and hemorrhagic glaucoma; and the choroidal disease which so uniformly precedes incipient cataract and upon which the cataract depends. In all of these cases, the blood vessel change which has so seriously disturbed the nutrition of the eye, has for months or years been steadily progressing, *pari passu* with that going on in the general system. In the serious ocular disease we witness the final outcome under peculiar anatomic conditions, but at the same time are furnished a rational explanation of their fatal character, and the disappointing results of all forms of treatment in their later stages. It is not reasonable to expect brilliant results from surgical procedures in an organ where the source of repair is cut off by narrowed and diseased blood vessels. Some forms of corneal disease, acute glaucoma, especially hemorrhagic glaucoma, hemorrhagic retinitis, vitreous opacities, complicated cataracts, albuminuric retinitis, with chronic nephritis and perivasculitis, are forms of ocular diseases that should always lead to a careful analysis of general conditions and will usually be found to prove but one of many other groups of symptoms pointing to the general impairment of the vital functions."

Difference in belief by able investigators would seem to throw a cloud upon the title to the claim of those who follow Deutschmann, were it not for the fact that we have again as able authors as those mentioned, who have written forcibly upon the subject of "Non-Albuminuric Bright's Disease," so that the presence, and amount of albumin always in any given case, it would seem, does not really bear a constant ratio to the gravity of the symptoms or the stage of the disease by any means. We are all of us familiar with the fact that a wide variation in this regard is noticeable from day to day, even in the same patient. The writer is acquainted with the case of an estimable professional gentleman whose urine varies in the amount of albumin which it contains almost with his daily walk and conversation. He has had periodical attacks of phlyctena for years, at which times his urine is always bad and his temper and nervous system worse. Relaxation, relief from business, a trip and cessation from worry clears everything up, except his smoky lens, which, while they are not cataractous, bespeak that peculiar opaline tinge of beginning sclerosis which comes on so many years before the appearances of the "cataract nigra." The decrease in the aggregated amount of albumin present, as compared with former years, is, it seems to the writer, only a pathognomonic sign of the "small constricted kidney," and not any indication at all of his physical betterment. One might faithfully say to him that it is only a race between life and sight as to which will go first.

Dr. Jas. Wallace, Assistant Ophthalmic Surgeon to the Hospital of the University of Pennsylvania has, by means of photographic enlargements of the microscopic appearances of thin sections of crystalline lens, near the region of the attachment of the suspensory ligament, brought out the fact that with an amplification of three hundred diameters he has been able to demonstrate the existence of minute fibers, in every respect answering to nerve fibers, running somewhat like a spiral figure 8 in and around the peripheral lens fibers, inclosing the cortical cells and other similar bodies, which sometimes

appear to be wandering cells, in a sort of embrace, which as it changes from time to time, assumes the appearance of peristalsis, thereby forcing along in the interfibrillar spaces these bodies, and keeping up a variable relation between the elements of the cortex and the fibers of the lens itself. These nerve fibers he is inclined to believe are directly in relation to the nerve fibers from the retina through the suspensory ligaments, and the zonula of Zinn. In this way he accounts for the rapid development of cataract, after the rupture of the zonula of Zinn without any injury to the lens. If these are nerve fibers, then they not only have to do with the physiologic action of the lens in its relaxation to light and accommodation, but they superintend and control the nourishment of the lens as well. The Doctor quoting from Richter's Organic Chemistry goes on to say that: "In the death of these, and other similar nerves, we have the development of a substance resembling *cholin* to which the name *neurin* has been given and which is very poisonous, having a very unstable formula, rapidly changing through a series of tri, tetra, penta and subsequent forms of methylamin, identical with *cadaverin*, *putrescin*, *saprin* and *mydatoxin*." A very pertinent remark closes this able article thus: "We notice cataract as a concomitant of diabetes, a disease in which gangrene of any part of the body is easily produced by a slight injury."

The most important point therefore, when it comes to the management of a case of cataract is the diagnosis. It is not enough to be able to recognize a grayish or pearly whiteness to the pupil, with a movable iris, and then come to the conclusion that the case is simply a senile cataract. Nor is it hardly justice to the patient or fair to the operator that none of the ophthalmoscopic details be made out during the earlier and incipient stages of cataract formation; the very time when all the important choroidal changes are liable to occur, and when they can with the greatest certainty be made out. Subjective evidence after maturity of the cataract, is of course in no case to be overlooked. The phosphenes, the qualitative and quantitative perception, the projection, etc., all these are important elements in the examination prior to the operation. But how much better it is when the operator has had several months or even a few years acquaintance with the case. So many little points which may be overlooked by the general practitioner, will have been from time to time made out; the condition of the inner tunics of the eye, the normal or abnormal condition of the vitreous, the sluggish or active condition of the iris, the susceptibility of the patient to atropin, or other drugs, the idiosyncrasies, whims, notions and temperament of the aged individual will have been learned, and all of those little peculiarities which go so far to make or mar our success, will have been taken into account, when the time comes to subject the patient to the trying ordeal of an operation. In those cases where a bladder derangement, a mild or a serious form of Bright's disease, a transient albuminuria from stasis in the general circulation, or some diabetic complication may exist, experience teaches us that some cases may so yield to proper treatment, diet, and regulation of the habits of life, as to make all the difference in the world in the final outcome of such an important and valuable operation as the removal of senile cataract.

CAN ANTITOXIN STATISTICS BE RELIED UPON?

BY GUSTAVUS BLECH, A.B., M.D.
SURGEON TO THE GERMAN FREE DISPENSARY.
DETROIT, MICH.

The many fiascoes in modern medicine have taught me a lesson, viz: Never to be the first and never to be the last one, to adopt a new remedy. Liberality is one of the first conditions for progress and success in medicine; conservatism, the preventative for poetic illusions and errors, undiscovered on account of the blinding effect of enthusiasm.

I have quietly watched the reports of cures of diphtheria with antitoxin, and have wondered how easy it is to catch the masses, even if one knows next to nothing about the *modus operandi* of a remedy. Beside, its origin and composition is mystery as yet, its preparation being controlled entirely by a few enterprising chemists. But neither this nor the fact that its introduction into the human system is apt cause a good many dangers like leucocythemia, shall be brought as an argument against its value; even the fact, that a good many eminent and thoroughly reliable physicians have reported their experiments with it as failures shall not be mentioned, and only one modest question shall be asked: Can antitoxin statistics be relied upon? I dare answer no, not always. I do not doubt for one moment the honesty of the reporters and their noble intentions; for the sake of the honor of profession, I will say that "figures will not lie," but I can not help assert that "figures will." The fact is, that every case reported as diphtheria, is indeed, not always true diphtheria. In some cases the microscopic examination alone was sufficient for a diagnosis, and that was false. In other cases the physical signs, the clinical picture was the medium, and that was false also. Both together, microscope and thermometer, eye and hand, must be employed to obtain a correct diagnosis.

Diphtheria, true diphtheria in spite of horse, jack-ass or any other quadruped's serum, is a grave, constitutional disease, the prognosis of which is always doubtful. It is exaggerated when one of my friends asserts, that he makes a diagnosis of true diphtheria post-mortem only; but there is some truth in that intended joke. There are plenty of poor children running around the streets with sore throats, follicular tonsillitis, rhinitis fibrinosa and never take a drop of medicine and get well. And in some of these a physician is called in, and a few hours later, the health inspector is placarding the house. If, by chance, the parents are smart enough to call in a more experienced physician, off goes the red sign. I had quite a number of such cases in my practice, but in one of my last ones, I had an encounter with our local board of health, which ended in my victory. The case I refer to is that of a little boy R. S., aged 4 years. He was taken sick with sore throat and nose, the latter bleeding on touch, membranes being expelled on sneezing. A reputable physician was called who pronounced it diphtheria. He sent a culture to the local board of health where Klebs-Loeffler bacilli were found. For some unknown reason to me, the parents discharged the physician and called me in to attend the case. I made a careful examination of the nose and throat found a somewhat accelerated pulse and a temperature below 100 degrees F. The boy ran from one room to another, and would not agree to

be confined to bed. While the mucous membrane appeared to be, on the first look, diphtheria, a closer examination revealed the double malady of follicular tonsillitis and rhinitis fibrinosa. Both affections simulate diphtheria almost to delusion. The clinical picture of a grave constitutional disease, high fever, etc., which symptoms are a *conditio sine qua non* for a diagnosis of true diphtheria, were absent. On the other hand some authors have lately classified rhinitis fibrinosa with diphtheria, but the best authorities in the old and the new world strongly object to such classification. The argument, that if the Klebs-Loeffler bacillus be found, the case must necessarily be one of true diphtheria, does not always hold good, as Baginsky and others have found the same bacillus in different forms of rhinitis and pharyngitis. While I must admit, that not every case of diphtheria is associated with a high temperature, constitutional depression, etc., such is the rule without any exception in nasal diphtheria. After nose and throat have been sprayed with hydrozone there could be found no microbe in the culture taken the other day.

The number of cases of this kind which I have successfully treated approaches closely to one hundred. If, according to the Board of Health of New York, Chicago and other institutions, they ought to be styled diphtheria, well then, what is the use of injecting blood serum taken from some animal? We have in hydrozone (30 volumes aqueous solution of anhydrous peroxid of hydrogen) a remedy which not only kills instantaneously the Loeffler bacilli, but also changes chemically the nature of the soil in which their spores can develop. Its deadly action is limited to vegetable cells (pathogenic germs) and it is the most powerful stimulant to healthy granulations, having no injurious action upon healthy animal cells. In fact, my experiment taught me that hydrozone is a safe and most reliable remedy to use in the treatment of diphtheria. On the contrary, I will say; How can we rely upon antitoxin?

203 E. Columbia Street.

A CASE OF STONE IN THE KIDNEY—NEPHROLITHOTOMY—RECOVERY.

BY W. D. HAMILTON, M.D.
COLUMBUS, OHIO.

Since Dr. Morris, of Middlesex Hospital, elaborated the operation for the removal of a stone from the kidney, the procedure has been frequently and successfully employed. The diagnosis of that condition is often difficult. In a sweeping way it might be stated that the inconstancy of the symptoms has prevented precision in the recognition and location of the disease. Again, other pathologic renal affections have shown symptoms suggestive of stone in that organ. Repeated attacks of renal colic, blood and pus in the urine, with the occasional passage of sabulous matter per urethram are strongly suggestive of it. Jordan Lloyd's valuable test led the writer to the diagnosis of stone in the kidney in the case about to be narrated. The hypothesis of renal calculus was offered, however, with mental reservations; for one surgeon, Dr. Jacobson, of Guy's, has reported not less than twenty-five exploratory lumbar incisions, where the symptoms of stone having been present some other condition was found. Early tuberculosis of the kidney, malignant disease involving the renal substance,

and the uric acid diathesis were the chief sources of error.

The inadequacy of puncturing the organ, and even its thorough palpation as final tests of the presence or absence of stone may be shown by the experience of Morris. The coterie of so-called stone symptoms was typical in a case in charge of this capable surgeon. Exploration through a lumbar cut, needling and renal incision brought negative results! The patient survived the operation. The symptoms recurred and we are compelled to admire the courage of Dr. Morris who removed the suspected kidney by the lumbar route. He could feel with the fingers no induration in its substance, when after nephrectomy the specimen lay before him. After incising it at several points he finally found, however, a stone of some size embedded in the renal tissue. The patient got well. Dr. Howard Kelley's recent article in the *News* will probably teach us much by the use of instruments of precision; for catheterization of the ureters, perfected as he states, will show us at least the kind of work done by either kidney. The patient, Mr. A., æt. 49, a merchant from Newark, Ohio, was brought to the writer by Dr. Notring, of that place. He had been an invalid for three years. His appearance was that of a man accustomed to great suffering; he walked in such a way as to favor the left side; he was badly stooped, and the concavity of the bend of his body was to the front and left. His side having been exposed, he was given a sharp punch in the lame loin, the thumb being forced in the direction of the kidney. He complained that he felt as if a sword had been stuck into him. Jordan Lloyd looks upon a statement of this kind by the patient, after receiving such a thrust, as being strongly suggestive of the presence of renal calculus. A uranalysis at the time elicited the following facts: Sp. gr., 1012; reaction acid; phosphates present; no casts.

About forty attacks of renal colic had occurred within the three years of invalidism preceding his visit. Each meant a week's illness in bed. Pain began commonly in the night, starting in the left loin. A so-called swelling showed itself in that region during these seizures and disappeared after them. More or less complete anuria accompanied this intumescence, and was followed by a copious discharge of urine each time. Increasing intensity of this loin-ache with frequent and painful dribbling acts of urination, were invariable accompaniments of these paroxysms. The free administration of morphia was necessary during them. Neither pus nor blood nor sabulous matter in the urine was ever observed by the patient or the attending physician. To make things more obscure, in a violent lifting effort, made about the time that his illness began, a left inguinal hernia was produced. He naturally attributed much of his discomfort to this fact. He was told that he had a stone in the left kidney. An operation was performed at his home on Aug. 4, 1895. The usual preparation was employed. Strychnia was given beforehand in thirtieth grain doses for a few days, for its stimulant and tonic effect; while the parts were cleansed and suitably prepared to minimize the risk of sepsis; ether narcosis; right lateral position; a hard pillow was placed beneath the right loin, so that the left costo-iliac space was thus put on the stretch and increased. A four-inch oblique incision was made, avoiding the pleura above and

peritoneum to the ventral side. The kidney was readily exposed; the finger was passed about the organ to separate the fatty capsule. On palpating its posterior surface toward the hilum a hard mass could be felt in the pelvis, which it well-nigh filled. Invaluable aid was rendered by the careful management of the anesthetic by Dr. Notring and by the strong upward traction of the ribs by Dr. Spear, so that the kidney could be brought well into the parietal opening. A probe was carried into the more accessible lower segment of the cortex, radially toward the pelvis, while the organ was steadied by the thumb and fingers. A stone was felt. The instrument in place served as a guide to the guarded bistoury with which the wound was enlarged; while a pair of angular Wells' forceps facilitated extraction of the stone. A drain was inserted into the loin; no vessels were ligated. Some shock supervened, but disappeared, however, within three hours. A few silk stitches were inserted. Some small sabulous fragments were discharged through the natural passages in the next few days. For a fortnight, urine was somewhat bloody, and afterward became cloudy.

Profiting by a previous experience in which after crushing a vesical calculus of the uric acid variety, the frequent voiding of cloudy urine had been a source of anxiety to the patient, the very free drinking of lithia water was advised and the urine became clear. He had quite recovered within a month so as to be able to pursue his occupation. The stone, a uric acid concretion, weighed 73.5 grs. It occupied the pelvis of the kidney which it almost filled, while the upper part of it lay embedded in the renal tissue. It might be well in closing to allude to the striking and misleading facts of the case, viz.: the absence of pus and blood and calcareous matter in the urine. He was at times, no doubt, a sufferer from acute hydro-nephrosis, as his history indicated.

CLINICAL LECTURE.

Extract from of a Clinical Lecture Delivered before the Senior Students at the Wisconsin College of Physicians and Surgeons.

BY JAMES A. BACH, M.D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOLGY.
MILWAUKEE, WIS.

GENTLEMEN:—Our first patient to-day is one of unusual interest. This young lady, as she tells us, about three years ago had the misfortune to receive a slight injury of her right eye, which injury was followed by deep infection, producing a plastic iridocyclitis. In due course of time the fellow eye became affected with a sympathetic inflammation, which practically amounted to an extension of the infection through the optic nerve sheaths, leading to similar results, i.e., a plastic inflammation of the uveal tract with extensive adhesions. The inflammatory process in both eyes has now come to a standstill, with the result that the girl has simply a perception of light left.

Covering one eye and moving this light across different parts of the visual field you will notice that she readily locates the light correctly; in other words, her light projection is good, showing that the perceptive organs are, to say the least, partially intact in every portion of the field. The readiness with which she locates this light, although only a very small amount can pass into the interior of her eye, owing to these dense plastic exudates in the pupillary field, gives us a reasonable assurance that if we can suc-

cessfully remove these dense obstructions to the light we may gain some very serviceable vision for this young lady. She has everything to gain and practically nothing to lose.

Before attempting to do this operation I should like to call your attention to some instructive features in this case. In the first place, by looking closely at the eyes with the assistance of oblique illumination you will observe that the anterior chamber is perfectly absent; the iris lying immediately behind the cornea conforming itself perfectly to the curvature of the cornea. A condition similar to this is often found after a neglected iritis with complete posterior synechiae, only that in these cases the iris does not adapt itself to the cornea, but bulges forward in the middle and is held down at the pupillary margins by adhesions, producing what is known as iris bombé. This bulging is produced by the filling in of aqueous humor in the posterior chamber, where it is chiefly secreted, which, however, can not find its way forward into the anterior chamber owing to the pupillary adhesions cutting off the communication between the chambers. In this case before you there is no bulging present, because there is no aqueous humor in the posterior chamber, the organs for its production having evidently been destroyed during the process of this deep and severe inflammation and adhesions, which is not the case when the inflammation is confined, or chiefly so, to the iris alone. These eyes evidently have lost their aqueous humor and with it the power to reproduce the same. As a rule, eyes of this kind experience a decided fluctuation in their tension. At about the time of the inflammation, owing to insufficiency of elimination of the internal fluids, the tension may rise very materially and may become $T = + 2$. The use of atropin in this stage is often not permissible, owing to this tendency. After the subsidence of this inflammation, the insufficiency of internal secretion of fluid, together with a gradual degeneration and shrinking of the contents of the globe, produced by the cutting off of the proper nutrition to these non-vascular structures, will gradually allow a decline in tension which often goes so far as to result in atrophy of the eyeball, known as phthisis bulbi. The tension of these eyes is as yet but very slightly reduced. If you will again look at the eyes under illumination you will observe the pupillary field to be very small, and instead of black as it ordinarily is, it is a yellowish white. This is a dense plastic exudate that has been thrown out during the process of inflammation and has become organized. But very little light can penetrate it. The iris looks slightly stretched and thinned; it has, however, not lost as much of its luster as one often finds in these cases.

We will now thoroughly cocaineize this eye and proceed to make a large iridectomy. We will, no doubt, find that the whole of the iris has become adherent to the lens so that after the iridectomy the endothelial pigment layer of the iris will remain adherent to the anterior capsule of the lens, necessitating the removal of the lens as well. These lenses, owing to the insufficient nutrition are cataractous, as a rule. As I now enter my knife at the limbus and penetrate the cornea, if you will watch closely, you will observe that it at once impinges upon the iris, but by careful manipulation I succeed, as you see, to make my corneal section, although too small for our purpose. I will now take these delicate scissors and on either

side enlarge my incision to sufficiency. As I grasp the iris with my forceps, I can feel distinctly its adherence to the lens capsule, and drawing a portion of it out it is snipped off. As anticipated, the pigment layer still rests on the lens. I now pass the cystotome into the anterior chamber and tear the capsule of the lens, which being completed the lens presents itself and is delivered without any difficulty. As you see, the patient is overjoyed at the fact of again receiving sufficient light to perceive objects. A similar case was operated at this clinic last year with a very satisfactory result. A fact that makes this case of special interest is that she has been refused operative interference from a number of oculists and she will indeed have occasion to feel grateful should the results prove such as we now have every reason to believe that they will be. It is very important in this class of cases not to operate while there are still active inflammatory symptoms present, because you are very liable to again lose through further plastic exudates the pupillary freedom gained by the operation.

Case 2.—This old gentleman, while a soldier in our late war, contracted trachoma, and has ever since been troubled with this unpleasant disease, not having received any special treatment for the same. Not only are his lids deeply infiltrated with the products of this disease, but it seems, on close examination, that the iris and other internal structures of the eye ball have suffered in consequence. He now comes to us with double senile cataract, which are mature. Under these conditions it always is a grave undertaking to open the eye ball, especially where the interference of the internal delicate structures is as great as becomes necessary during the removal of a cataract. The chances for infection become a serious consideration. Although he has been under treatment for his granulations for some time now, yet the conjunctival sac is still not in a sufficiently healthy condition to justify subjecting this man to the operation of extraction. In these cases it is a good plan and one that I always pursue, to divide the operation into two parts and in that manner lessen very materially the chances for infection. By making a preliminary iridectomy to-day only, the chances for infection are not great and in the course of a few weeks, having received more treatment for the trachoma, we can with reasonable safety remove the lens. Any unhealthy condition of the conjunctival sac where this can be done ought to always be remedied before making the operation for cataract, otherwise we may expect from time to time to lose eyes from infections. I believe it is chiefly owing to the great care I take in preparing my cataract patients that I have not sustained a single loss of an eye through infection after cataract extraction; my success has been uniform.

Privilege not Waived. In the case of *Barker v. Cunard Steamship Co.*, decided by the general term of the supreme court of New York, Dec. 18, 1895, the court holds that it was not error to refuse to permit the defendant to prove by a certain physician the condition of the plaintiff when he entered a hospital, and the statements made by him in respect to the previous condition of his health. The knowledge of this witness was acquired from an inspection of and conversation with the plaintiff while the relation of physician and patient existed between them, and was privileged. This privilege, the court declares, was not waived by the plaintiff's having called other physicians to testify to his condition anterior and subsequent to the time he was in the hospital.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 86 FIFTH AVENUE, CHICAGO, ILLINOIS.

W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, JANUARY 25, 1896.

MEDICAL EDUCATION IN THE UNITED STATES
IN 1893.

The advance sheets of the report of Bureau of Education for 1893, just at hand, are full of most valuable information. This is an unusually bulky report. It contains all of the educational work presented at the world's congresses at Chicago. The discussion of these papers must be left to educational and literary journals and the present notice confined to the statistic material relating to medical schools. It is impossible to overlook the fact that this report is unusually incomplete in its treatment of medical education. The fact that nearly all medical schools are private schools may account for the reluctance of the Bureau in making full financial and other statistic reports of their condition and progress. The schools of theology are also private and yet they are much more fully reported. Taken as a whole, this report prepared by A. ERSKIN MILLER, will be found very useful and encouraging. The strong and certain drift to the four-year course is manifest. There is a gradual improvement in the material equipment in nearly all medical schools and a tendency toward enlarged, even bulky faculties. The clinical and laboratory facilities seem to be improving; and better than all, the requirements for admission are steadily advancing. The report should give great credit to the various State examining boards and to the Association of American Medical Colleges for these improvements. The number of medical students enrolled has gradually increased from 12,238 in 1888-89 to 16,130 in 1892-93, while at the same time the percentage of the enrollment graduating has fallen from 27.1 to 24.9. Very few schools require study with a preceptor. Study of medicine in the

United States has become study at the college and in the hospital. It means perhaps too exclusive study in the classroom, in the laboratory, at the clinic and in the post-mortem chamber. It can not be doubted that this too exclusive scholastic trend of medical education will produce more scholarly but perhaps less successful practitioners.

It is hard to understand the gradual and uniform decline in the number of college graduates who study medicine. It would be natural to expect an increase of college men in medicine with every improvement in medical teaching. But at Harvard, for example, where there has been a steady advance in all that can be called better medical education, the ratio of college graduates to the total enrollment has fallen from 54 per cent. in 1884 to 23 per cent. in 1893. It may be that the reputation which Harvard attained through the influence of the large ratio of college men led to an inundation of students without literary degrees, and a real or apparent falling off of the better educated men.

There were 132 medical schools in the United States in 1893. Of these 2 were preparatory, 94 regular, 16 "homeopathic," 10 "eclectic," 2 "physio-medical" and 8 graduate schools. The total enrollment of these colleges was 28,900 in the school year 1892-93, 16,130 were in the regular and 1,445 in the homeopathic schools. There were 827 women enrolled in the 36 regular schools admitting women, out of an enrollment of 1,302 in all schools of medicine. For comparison it is well to notice the fact that there were at this time 142 theological schools with 7,856 enrolled and 1,502 graduating students, a gradual increase of 1,000 students in five years. And again, there were 63 law schools with 6,776 enrolled and 2,400 graduating students, an increase of almost exactly 3,388 students in five years.

It is interesting to study the grouping of the enrollment in the regular schools. Of these 16,130 students, the north Atlantic States claim 5,182; the north central States 5,229; the south central States 3,048; the south Atlantic States 2,192; and the Pacific States 479. The schools of New York, Pennsylvania, Missouri, Illinois, Kentucky, Maryland and Tennessee claim respectively 2,287, 1,867, 1,394, 1,386, 1,342, 1,111 and 1,060.

During the year 1892-93 one school, the University of Pennsylvania, had more than 800 students; three schools, Jefferson, Bellevue and Rush, had more than 600 and less than 700 students; two schools had more than 500 and less than 600 students; four schools had more than 400 and less than 500 students; four schools had more than 300 and less than 400 students; twelve schools had more than 200 and less than 300 students; twenty-three schools had more than 100 and less than 200 students; and thirty-nine schools had less than 100 students.

The annual fees varied between \$200 and \$28, and the graduating or examining fee from \$30 to \$0. All the schools except a few in the South were three-year schools; a few in the North required four years. The value of the buildings and equipment varied in the several schools between \$320,000 and \$12,000. The number of full professors was never less than seven and sometimes as many as twenty-eight. While one school had two assistants, one had sixty-five such teachers.

There is no discussion in this report of the course of study in the various medical schools in the country, nor is there any adequate presentation of the work of the various examining bodies. No more valuable work could be done for medical education than the presentation of the courses of study and the methods of such schools as excel in the teaching of particular branches or in particular directions.

THE DIAGNOSIS AND TREATMENT OF PERFORATION OF ULCER OF THE STOMACH AND DUODENUM.

Among the more dangerous symptoms of gastric ulcer, perforation has attracted special attention. The diagnosis and the treatment of this condition are made the subject of a special study by BLUME,¹ the results of which merit the interest of medical men in general. Of late years surgeons have busied themselves with perforation-peritonitis and occasional successful operations for perforation of the stomach have been reported. It is consequently an opportune time to review the results of the methods of treatment hitherto in vogue and to make clear the diagnosis and prognosis of perforation of the stomach in order to estimate the probable chances of the success of the new treatment.

There are recorded cases of recovery after perforation of the stomach into the free abdominal cavity without operation. FENWICK² and LIEBERMEISTER³ both describe such cases in some of which the correctness of the diagnosis was confirmed by post-mortem examination. The idea that extensive or diffuse perforative peritonitis need not always be a fatal disease has received support in some of the cases treated by operation. Diffuse purulent peritonitis has been cured by means of incision with, as well as without, efforts at disinfection of the peritoneum and even after complete suture of the incision without drainage.⁴

BLUME briefly reports sixteen instances of acute and subacute cases of perforation of the stomach treated without operation. These cases were from PROFESSOR TRIER's division in the Kommune Hospital in Copenhagen. All the cases were examined after death. The seat of the perforation was in the ante-

rior wall of the stomach in fourteen cases, in the anterior wall of the duodenum in two, and twice in the posterior wall of the stomach. In fourteen of the cases the post-mortem showed a diffuse peritonitis. In eight cases distinct evidences of an effort to close the perforation by means of adhesions were demonstrated. The length of time between the occurrence of the perforation and death varied from less than twenty-four hours to ten days, showing that in many cases there would have been time enough to consider the treatment and eventually operate.

BLUME then details four cases in which the symptoms after the perforation ran a more chronic course because peritoneal adhesions limited the peritonitis to the vicinity of the perforation. In none of these cases could a correct diagnosis have been made during life.

In a third series are reported seven cases of recovery from the perforation without operation. In all these cases the clinical data include observations that verify the diagnosis of gastric ulcer and records of the objective signs of the peritonitis whether it was diffuse or circumscribed; the latter was the case in four of the seven cases. Three of the patients entered the hospital forty-eight hours after the perforation, one thirty-six hours, one eighteen hours, and two less than twenty-four hours. The medicinal treatment consisted exclusively of opium and morphin. The feeding consisted in giving one teaspoonful of iced milk every fifteen minutes or one-half hour when the patient was awake, which quantity was gradually increased after a few days. Rectal feeding was not employed. The rationale for this somewhat unusual procedure was the fact that it is so important to keep up the normal functions of the stomach in order to hinder the regurgitation of intestinal contents into the stomach from which they would run out into the peritoneal cavity. BLUME lays great stress on this mode of feeding and the results seem to warrant his criticism of the remark of MIKULICZ⁵ that "in perforative peritonitis the physician stands as an idle observer." The importance of reliable, trained nurses and of the suitable position of the patient is also emphasized.

BLUME then reviews seventeen cases from the literature, especially the English, in which operation was performed. The cases are arranged topographically into four groups: *a*, perforation in the region of the pylorus and duodenum, three cases with two deaths; *b*, perforations in the posterior wall, one case, recovery; *c*, perforations in the anterior wall, four cases with three deaths; *d*, perforations near the cardiac orifice, nine cases with six deaths. Some of the conclusions drawn from the histories of these cases are the following: The authors believe the operation should be made as soon as possible after

⁵ Volkmann's Sammlung, No. 262, 1885.

the perforation. Chloroform narcosis is said to be tolerated with astonishing ease. The incision is made in the median line between the xiphoid appendix and the umbilicus; transverse incisions may become necessary in order to reach the point of perforation. The treatment of the perforation itself is the essential act of the operation. The accessibility to the opening varies greatly in the four groups of cases; in group *a* the perforation is readily found; in group *b* access to the perforation is to be gained by cutting through the ligamentum gastro-colicum, when the stomach may be turned upward and the point of perforation brought into view. The perforation is easiest to find when situated on the anterior surface of the stomach (group *c*), but the acuteness of the angle formed by the costal arches may encroach seriously upon the room necessary to suture the opening; in the last group, *d*, the perforation is situated high up behind the chest wall and inasmuch as the stomach can not be pulled down the treatment of the opening in this group is very difficult and in three cases suturing of the perforation had to be abandoned as impossible, while in two cases the perforation was shut off from the rest of the peritoneal cavity by fastening the stomach to the abdominal wall, and in one a cure was obtained. The treatment of the peritonitis consists of flushing with a warm, sterile, indifferent fluid or dry sponging with sterile gauze. Drainage of the peritoneal cavity was employed in nine of sixteen cases in which this point is referred to, three of the nine recovered; seven cases were treated without drainage and of these three got well.

Comparing the cases treated medically with those treated by surgical means, BLUME states that the results of the medical treatment as shown in the series of cases described by him are quite respectable, and that the possibility of a cure without operation has been definitely established, but nevertheless, the secure closure of the perforation by suture would hold out more definite hopes for recovery. In order to limit the operative interference to a minimum the diagnosis should be as certain as possible in order that the correct incision might be made at first and not, as has happened, between the umbilicus and the pubes, followed by exploration of the genitals, the cecum and the ileum before the attention was directed to the stomach where the opening was situated. And then BLUME advocates strongly the method of nourishment described in the operated cases as well. The idea that the stomach must be placed at absolute rest and remain empty is illusory. Unless the normal secretory functions are kept at work regurgitation of intestinal contents may follow.

THE Berlin Association for Int. Medicine has been devoting much time lately to the study of phenacetin poisoning.

PHYSICIANS AS LEGISLATORS.

The Cincinnati *Lancet and Clinic* announces, perhaps a little prematurely, that the grand old Commonwealth of Kentucky has honored itself by the selection of DR. GODFREY HUNTER to represent the State in the United States Senate for the next six years. Whether or not this is yet actually the fact, it is a truth that as physicians we may all feel a legitimate interest in seeing our profession represented in the highest legislative body of our nation. There seems to be an impression abroad in this country that physicians like clergymen are debarred from political honors and that there is no need of their advice in legislation. On the part of the profession itself there is perhaps too much of a notion that politics is a dirty business, unworthy of the attention of professional men, a sort of pitchy mess that can not be touched without defilement. That this is true to any extent is due to the fact that decent men keep clear of it and the condition will never be improved by keeping up and acting upon the prejudice. There is no class of men better qualified to purify politics than honorable physicians, who preserve the high ethical standards of their profession. To say that they will be injured by the associations or that the profession will be degraded by its members taking interest in public affairs, is to state what is not at all a necessary truth; the fact is that those who can be thus hurt are already past the danger point, and the profession is already sufficiently degraded by those who have aided in making too many of our public charities to a large extent mere political machines. What is needed is the entrance of high grade medical men into our legislatures and Congress, and their aid and advice in the framing of our laws. The public welfare is the aim of all legislation, and among its first essentials if indeed if it is not the first, is the public health. Legislators more than any other public functionaries need enlightenment on sanitation and beside these there are a thousand questions that may and continually do arise in constructing and amending the laws where medical knowledge is of the highest value and where the lack of it may be disastrous in its effects. There is need, moreover, of the medical element in our halls of legislation; no class of men are closer to the people and better know their needs than do physicians, and a high professional training and education is no bad preparation for public service. The record of a RUSH, a MITCHILL, a VIRCHOW and a VERGA is an evidence of this fact, and there is actual need of the employment of this special class of talent in this country at the present time. A sprinkling of first-class medical men in Congress would be a most desirable addition.

To have it so, would be in accordance with the best precedents and traditions of our country. In the days of the Revolution when educated doctors were

few and far between, and there was not a single medical school in the land, five out of the fifty-six signers of the Declaration of Independence, DRs. RUSH, WOLCOTT, THORNTON, BARTLETT and HALL, were members of our profession, thus making over 9 per cent. of the members of the first Continental Congress: a proportion that well showed the rank of our profession in popular estimation in those times that tried men's souls.

NAVAL APOTHECARIES.

Not every vessel in the navy carries a medical officer: yet every vessel, however insignificant, has both captain and apothecary, representing opposite ends of the pole in the matter of personal and official consequence. The naval apothecary has come down to us from the time of BENBOW. He was only a "man before the mast" then, and he is only a "man before the mast" now, though his qualifications have risen with the times and the attempt is now made to secure graduates in pharmacy for those positions. It is not surprising, therefore, that association with the coarse, illiterate denizens of the berth-deck, which befitted the mere manipulator of an enema syringe or the dresser of a suppurating bubo, should be repulsive to young men who are able to pass the examinations of the modern schools of pharmacy, nor that they should demand, at least, an equality of position with the paymaster's clerk, who needs only know how to read, write and cipher.

The apothecary on board ship is the right-hand man of the medical officer. He compounds and administers the remedies prescribed, and beside his work as surgical and clinical aid, he performs such clerical duty as may be required, and in these days of complicated forms of returns of property, inventories, requisitions, vouchers, explanatory letters and other official communications, this is no inconsiderable labor, especially on board a flagship at sea or at a hospital on shore. If the ensign who prepares or copies the commanding officer's letters, or the pay clerk who adds up columns of figures and witnesses the payment of money to the crew, are fit to wear the uniform of an officer and have quarters in what used to be known as the steerage, there can certainly be no impropriety in the man who is required to know and to perform the complex operations of the pharmacopœia living under the same conditions.

In nearly other civilized country in the world than the United States, the pharmacist is held in high esteem, and the elaborate report of the special committee on legislation of the American Pharmaceutical Association appointed in 1894, consisting of a member from each State and Territory and of which Dr. GEORGE F. PAYNE, State Chemist, Atlanta, Ga., is chairman, exhibits in detail the status of pharmacists in the armies and navies of European States, much of the information having been translated from

the *Pharmaceutische Zeitung* by OTTO HOFFMAN, A. B. In some of these countries pharmacists are officers with definite high rank. In France the Inspecteur Général is a major-general. In Russia, Counselor of State is the highest title obtained by the pharmacist by virtue of his rank. In Belgium, the chief pharmacist has the rank of lieutenant-colonel, two that of major, with others in grades down to that of second lieutenant. In Italy, one chemico-pharmaceutical inspector has the rank of lieutenant-colonel, one director and six head pharmacists that of major, twenty-seven are captains, thirty are first lieutenants and forty are second lieutenants. In Holland and the Dutch colonies, the military pharmaceutical service is performed by military pharmacists, who rank as officers and belong to the corps of sanitary officers. The directing pharmacist is a lieutenant-colonel with a salary of 9,000 guilders, about \$3,600. The directing pharmacist of the second class receives 7,800 guilders (\$3,120); pharmacists of the first class 4,800 guilders (\$1,920) and of the second class 2,700 guilders (\$1,080). "To this is added a free dwelling or a compensation for such, which ranges between 500 and 2,000 guilders (\$200 to \$800) according to rank and station." In Switzerland, the staff pharmacist has the rank of a major and in Germany and Austria a colonel's grade is the blue ribbon to which the military pharmacist aspires.

In the United States navy he is an *enlisted man*. In the army he is known as the Hospital Steward. His pay begins at \$45 a month, and never exceeds \$50. In the navy his designation is Apothecary, and he rates as an enlisted petty officer, sandwiched between the yeoman and the bandmaster; but inferior in pay and position to machinists, chief carpenter's, gunner's and boatswain's mates, chief quartermasters and masters-at-arms. Nevertheless, the candidate for enlistment as an apothecary in the navy

"Must pass the usual physical examination, and must present testimonials or certificates as to character, good habits and sobriety. They are also required to pass a satisfactory examination in the following subjects, viz.: 1. *General education*. Arithmetic, orthography, writing (legible and grammatical), geography and history of the United States. 2. *Professional*. Materia medica a knowledge of the botanic name, origin, habitat, preparations and doses of the drugs recognized by the Pharmacopœia; pharmacy a knowledge of the various pharmaceutical processes employed in the manufacture of the various officinal and official preparations, and the relative proportions of the more important drugs entering into the composition of these preparations; chemistry a knowledge of chemie symbols, the formulas of the more important official chemicals and of the reactions produced by the combination of chemicals; toxicology a knowledge of the symptoms of toxic doses and antidotes of poisons. The recognition of crude drugs, the making of ordinary pharmaceutical preparations, the compounding of prescriptions and the criticising of prescriptions incorrect by reason of pharmaceutical or chemie incompatibility or from dangerous doses. A practical knowledge of bandaging, *minor surgery*, application of dry and wet cups is desirable for which the applicant will be given due credit."

He may be both an A.B. or B.S. and a G.Ph., but he must live on the berth-deck, an enlisted "man before the mast," with the pay of a boilermaker, \$60 a month, and less than to that of the master-at-arms (\$65) and machinist (\$70). Boatswains, gunners, carpenters and sailmakers are warrant officers with special mess and quarters and pay ranging from \$700 to \$1,800, and all that the apothecaries themselves are asking in a bill before Congress is that they shall be raised to the level of these warrant officers, with equivalent rank, pay and privileges. Many old officers of the navy, however, are of opinion that the grade of warrant officer should be abolished, the duties of the boatswain, carpenter and sailmaker being performed by their mates, who are mechanics, and as such properly are of the rank of machinists, boilermakers, blacksmiths, plumbers, painters and the like, while the gunner should give place to the ordnance lieutenant, to which promotion from the ranks should be provided. The pharmacist should become a "steerage" officer, along with the pay clerk, as befitting his general culture and professional education. If this be done, the old-time apothecary, who was shipped for a cruise, the "Doc" of the berth-deck and fore-castle, who could never be intrusted with the key of the medical storeroom lest he drink the wines and liquors provided for the sick, who was suspected, with good reason, of having a considerable surreptitious practice among syphilitic and gonorrheal sailors and marines seeking in this way to escape restriction of their liberty, who on shore paraded himself as one of the doctors of the vessel, whom it was never safe to permit to dally with metric subdivisions of strychnin, morphin or arsenious acid, and who, indeed, usually managed to clandestinely possess himself of a set of apothecary's weights to avoid shipwreck on the shoals of grams and cubic centimeters, will have disappeared from the service, and his place be filled by a gentlemanly, intelligent, educated young man, whose pride in his G.Ph. will be creditable to the navy and an assurance that he will not attempt to usurp the functions and wear the borrowed clothes of his medical superior.

MEDICO-MILITARY TITLES.

We have now neither medical directors nor post surgeons in the medical department of our army. The revision of the Army Regulations issued a few weeks ago, abolished the one, and the first circular of the present year, published from Headquarters of the Army January 2, has done away with the other. The medical officer on the staff of a general commanding a department, an army or an army corps, known during the greater part of the past century as a medical director, has now become the chief surgeon of the command, to give uniformity to the titles of the staff

functionaries, who are the chief quartermaster, chief commissary, chief paymaster, etc. The recent circular brings the staff of a post commander into uniformity with this system of nomenclature, by directing that hereafter the senior medical officer of a military post will be known officially as the surgeon, and the other officers as the adjutant, the quartermaster, the signal officer, etc.

These changes by the present energetic Secretary of War must meet with general approval as indicating, with business-like directness and brevity, the office held by each staff officer. So well do they commend themselves to us, that we are inclined to inquire why a series of complex titles are retained to express the position of individual officers in addition to the now simplified title of the office which they fill. The chief surgeon, chief quartermaster, or chief commissary of a department may be an officer with the rank of colonel, and the designation of assistant surgeon general, assistant quartermaster general, or assistant commissary general, according to his corps; or one with the rank of lieutenant-colonel, and the personal status of a deputy surgeon general, deputy quartermaster general, etc., or he may be merely a surgeon, quartermaster, or commissary, with the rank of major. There seems to be no need of the special designations of deputies and assistants to the chiefs of military bureaux, as the responsibilities and duties undertaken and performed by officers having these titles may be performed as well by an officer with the rank of major. These special designations are high-sounding titles which mean nothing, puny survivals in modern life of the grand, mighty, illustrious and supreme so and so's of the dark and middle ages. The rank, pay and status of officers senior to majors are defined sufficiently by the rank of lieutenant-colonel and colonel, without the appended titular embellishments.

This leads us to realize that there is as little need for special designations for surgeons below the rank of major as for those above this rank, as little need to detract from the dignity of a surgeon below the rank of major by calling him an assistant surgeon as there is to attempt to add to the dignity of an officer with the rank of lieutenant-colonel or colonel by calling him a deputy or an assistant surgeon general.

Before entering the army a candidate for position in the medical staff must have fulfilled all the legal requirements, to authorize him to practice medicine and surgery. In civil life he is a physician and surgeon; but when he enters the army he ceases officially to be what he legally is, and becomes an assistant surgeon. His pay, emoluments and official status are defined sufficiently by the junior rank of lieutenant or captain; and no object is effected by prefixing assistant to his professional title. The position we assume is, that the Secretary of War could, with ad-

vantage, go further than he has gone in the direction of business-like brevity and uniformity in the titles of our professional brethren in the military service. Graded official titles outside of those defining rank are an encumbrance also among the quartermasters, and members of the other staff corps, but we have no particular concern about them.

THE INSIGNIA OF THE ARMY MEDICAL DEPARTMENT.

The selection of insignia for the medical department of the army has been before the officers of that department in an unofficial way for many months. It is now before them officially, and the question will no doubt be settled promptly. The Surgeon General has appointed a board to consider the subject, and has requested officers who have suggestions to make to communicate them to COL. CHARLES H. ALDEN, Assistant Surgeon General, the president of the board.

At the present time the medical department is practically without any distinctive insignia. From early times the letters M. D. were embroidered in silver on the black ground of the epaulettes or shoulder knots, but this lettering was always as distasteful to medical officers as the P. D. and Q. D. of the pay department and quartermaster's department were to the officers who had to wear them. Three or four years ago, when some changes were made in the uniform, the national shield in gold was proposed and approved as a substitute for the lettering of the medical department. The shield, however, has never given general satisfaction, inasmuch as although emblematic of defense, it has no association with defense by medical men against disease or death; and, moreover, a shield in silver with thirteen stars has already been assigned as the insignia of the adjutant general's department. These objections led to the agitation which has been going on for some time and no doubt to the recent appointment of a board to settle the question.

So far as we can ascertain, the majority of the corps is in favor of the red cross of the Geneva Convention in an artistic setting of embroidered gold; and this seems to be the most appropriate and distinctive emblem that could be adopted. All civilized nations have signed the Treaty of Geneva, and adopted the red cross as their military hospital flag, so that the association of this emblem with an army medical department is widely known. The seventh article of the convention requires that all hospitals and ambulances shall carry, in addition to the flag of their nation, a distinctive and uniform flag having a red cross on a white ground. Moreover, in time of war all the members of the staff of the hospitals and ambulances must wear an arm badge or brassard having this emblem on it to insure them the neutrality guaranteed by the treaty. Our own hospital corps wears the cross on the bras-

sart. What more appropriate, therefore, than that the red cross should constitute the insignia of the medical department? Some officers have objected to it as being the emblem of the American Branch of the Red Cross International Society; but it is the emblem of this society only because it is the regulation hospital flag of the army. The members and employes of the Aid Society, if they are to constitute any part of the staff of a military hospital in time of war, must wear the cross in accordance with the terms of the treaty. They become, in fact, a part of the army medical department.

NEW INSTRUMENTS.

COVER-GLASS FORCEPS.

BY O. E. LINJER, M.D.

STARBUCK, MINN.

To those who are familiar with microscopic technique the following illustrations of a cover-glass forceps devised by me are self-explanatory. Clinical microscopy demands the simplest as well as most rapid methods consistent with accuracy. None of the many cover-glass forceps now in use are adapted to modern microscopic work. For staining sputum, pus, blood, etc., the complete process, from fixing to placing of cover-glass on slide, may be carried out while cover-glass is held in forceps.

The following advantages are claimed for these forceps: 1. The cover-glass while on its flat side can be rapidly picked up from any surface whether glass, marble, wood or paper. 2. The cover-glass is held level, firmly and anatomically. 3. No possibility of cover-glass slipping out of or breaking while held in forceps. 4. Hands of operators are kept free from stains and acids. 5. The edge only of cover-glass being grasped and held by forceps, admits of the whole surface of the cover-glass being stained. 6. Cover-glass can be drained by placing forceps on the side.

These cover-glass forceps are manufactured and sold by Chas. Truax, Greene & Co., of Chicago. Every pair of forceps, if properly made, possesses the above mentioned advantages over the clumsy forceps formerly used.

CORRESPONDENCE.

Treatment of Typhoid Fever.

LEBANON, IND., Jan. 21, 1896.

To the Editor: From time to time we read in this most excellent journal articles extolling the Woodbridge treatment for the most dreaded of fevers in our country. In the JOURNAL of January 11, this year, there is a well-worded article on this subject in which the writer rids the patient of danger and jests at the alarm of the family in this most dreadful disease. I will never forget what Prof. J. M. Da Costa said in the beginning of his lectures on fevers: "Gentlemen, this is the fever of this country; *uay*, it is the fever of the world," and surely Prof. Mitchell's adage of piloting the ship

clear of breakers is as true to-day as the day it was spoken. No doubt Dr. Woodbridge has added some enthusiasm to our modern principles of typhoid fever treatment. But let us not lose our power of reasoning and accurate observation until we see more of this treatment. I read with interest his paper at the Baltimore meeting, and with more interest the discussion by Drs. Pepper and Osler, in which the former stated that each time we had discovered a panacea in medicine or plan of treatment for this disease, we were disappointed in the next epidemic by a frightful mortality.

Typhoid fever, in all probability, has existed for ages past, but it was left for an American physician about sixty years ago to catalogue it as a distinct disease. Now from one decade to another we are learning to treat it better, each enthusiast on the subject adding his mite. Dr. Graves, of Dublin, wanted it engraved on his tombstone how he fed fevers. And now let me ask Dr. Woodbridge and his followers if we take from a typhoid fever patient proper hygienic surroundings, proper feeding and good nursing, what good will his or any other treatment do? My partner, Dr. C. J. Lidi-kay, and I bought of Parke Davis & Co. the Woodbridge medicines and commenced the use of them last year in good faith. Our first patient was a most favorable one for the treatment, a formerly healthy girl 12 years old, in a family with two other cases of typhoid fever. We followed the plan in minute detail, and the fever went through its regular stages, lasted four weeks, and we could not see that the treatment did any more good than any other sensible plan of management. We tried it faithfully on fourteen cases in two families on the same farm who used the water out of a polluted well. It never modified nor shortened the duration of a single case, for they all went through the regular stages. They all got well but one, who took double parotitis while convalescing. Five other children out of one other family who visited this farm took the fever and two died, one from hemorrhage and one from the severity of the lesions after four weeks' sickness. We treated over forty cases of all grades of intensity with only the loss of these three cases. And at last treated my only child last October through a typhoid fever. I tried the Woodbridge treatment up to the second week, when her stomach rebelled against the soft capsules and emulsion of the same. We then nursed her with just enough medicine to control symptoms. The fever reached 100 degrees four successive days the latter part of the third week, and we have nursed her three months since to tide her over the effect of this awful fever, encountering several dangerous breakers along the line.

Dr. Osler said the best thing he could see about this treatment was that the medicine was harmless. Woodbridge has emphasized one principle that will last, and that is that the bowel will stand more cleaning out with less danger than was formerly thought. Typhoid fever still holds sway over patients. We are between *Scylla* and *Charybdis* in its treatment, and it is a plague to any family or community. W. F. BATMAN.

The Royal Colleges and the Women.

To the Editor:—The recent action of the Royal Colleges of Physicians and Surgeons, England, in declining, by a narrow vote, to grant women their diplomas, is indicative both of the remaining prejudice against women doctors and the progress of their efforts for complete recognition by the profession.

The two chief arguments against them, aside from natural unfitness, were that they commonly entered the profession from improper motives, and that they had contributed nothing toward its advance. It is thus quite evident that some of our professional brethren across the water, have been expecting too much from the "gentler sex," for the very same arguments will apply equally well to not a few of the masculine denomination. Also the fact seems to have been overlooked

that the "new" woman is still comparatively new and has hardly had time to evolve that increase of brain and the de-sexing process which are finally to fit her with that keen, cool, deliberative mind requisite to rule the earth on scientific principles. The "new" woman may not possess the charms of a Cleopatra, but she craves her power and if she cannot attain it the one way, why should she not try another? There can be but little objection to giving her every privilege within the bounds of propriety, for in so doing her superiority in some department of medicine will the sooner be demonstrated, or her mania the sooner ended.

Doubtless some enter the profession from the loftiest motives, and do credit to it, and whether or not, after all is considered, they have mistaken their calling, is for them individually to judge. It is to be hoped that ere long they will have no occasion to complain of unequal privileges in such an enlightened city as London. J. S. C.

A Knotted Umbilical Cord.

BERWYN, ILL., Jan. 16, 1896.

To the Editor:—A rather unique case occurred in my obstetric practice at this place last week. Mrs. S., who was under my care and expected to be confined late in February, sent for me early the morning of January 10. Upon arriving at the house I found my patient in the midst of labor, regular pains, very frequent and severe. Examination revealed dilated os, breech presentation, no evidence of fetus being alive. A short time later delivery was accomplished. The fetus was dead. Stage of development was that of a seven-months' fetus. It weighed about three pounds, and gave evidence of having been dead some little time, as it was considerably macerated. Upon examination of the cord I found a tight knot about midway between fetus and placenta. This undoubtedly had caused fetal death, which precipitated labor. The mother had not felt life for several days previously. Possibly this case may be of interest as evidence that the fetus does enjoy considerable latitude of motion in utero.

Very respectfully yours, ARTHUR MACNEAL, M.D.

Suspensio Uteri or Ventro-Fixation of the Uterus Its Influence upon Pregnancy and Labor.

To the Editor:—Having recently had some unfortunate experience concerning suspensio uteri upon parturition, I feel that it is highly important that this question be settled in an authoritative way as soon as possible. The only way to determine the question is by studying the actual results as seen in the practice of all operators. I will be much indebted to any one having had a case of pregnancy following suspension of the uterus, if he will communicate the details of the case or cases to me.

Very truly yours, CHARLES P. NOBLE.

1637 N. Broad St., Philadelphia.

Sexual Perversion.

WASHINGTON, D. C., Jan. 20, 1896.

To the Editor:—Having noticed in two of your late issues that correspondents ask for the definition of the word *tribadism*, I will call attention to the very full and comprehensive article by Dr. Irving C. Rosse, of Washington, D. C., on "Unnatural Crimes," in vol. II, p. 493, of Witthaus and Becker's "Medical Jurisprudence." In this valuable and instructive paper, your correspondents will find detailed information as to the various forms of sexual perversion as observed by neurologists and as treated from the view point of medico-legal knowledge. Trusting the reference, as already given above, may be of service to your correspondents. I remain, yours respectfully,

EDWIN L. MORGAN, M.D.

2315 Pennsylvania Avenue, N. W.

Transactions of XI International Medical Congress.

CAMBRIDGE, MASS., Jan. 20, 1896.

To the Editor: In the Miscellany of the JOURNAL of January 18, page 142, inquiry is made as to what time the volumes of the XIth International Medical Congress at Rome, Italy, will be ready for distribution.

In answer, I would say that I received some months ago direct from Messrs. Rosenberg & Sellier, Libreria Internazionale, Via Bogino 3, Torino, Italy, volume II, and on January 18, through the Bureau of International Exchanges, Smithsonian Institution, Washington, D. C., volumes III and IV.

For members to receive their volumes promptly it will be necessary to make remittance of 7.50 francs to the house of Rosenberg & Sellier, Libreria Internazionale, Via Bogino 3, Torino, Italy, to meet the expenses of the distribution.

Sincerely yours, AUGUSTUS P. CLARKE.

A New Medical Society.

KANSAS CITY, MO., Jan. 16, 1896.

To the Editor: On April 7, 10 A.M., at the Midland Hotel in Kansas City, Mo., a meeting will be held for the purpose of forming a society of laryngologists, rhinologists and otologists. All Western physicians engaged in the above specialties are cordially and earnestly invited to be present and aid in the work. Kindly give this a notice in your JOURNAL.

HAL FOSTER, M.D.

BOOK NOTICES.

Diet in Sickness and in Health. By MRS. ERNEST HART, with an introduction by SIR HENRY THOMPSON, F.R.C.S. 8vo, pp. 219. London: The Scientific Press; Philadelphia: W. B. Saunders. 1895.

"No man," says Sir Henry Thompson in the introduction, "is a really accomplished physician or surgeon who has not made dietetic principles and practice an important part of his professional education." Those who had the pleasure of meeting the accomplished authoress in the "Irish Village" at the World's Fair in Chicago, will not be surprised to learn that she has managed to sandwich many an interesting sketch from the scenes of her travels, which add piquancy to the pages of a scientific book, without in the least detracting from its high professional standard. In speaking of tea, she says, pp. 34 and 35:

"Every Japanese household, however poor, possesses a large metal teakettle, and a small porcelain or pottery teapot. Into the tiny teapot is placed a small amount of fine green tea. On this is poured water not quite boiling. Without allowing the water to stand on the leaves more than a moment or two, the tea is poured into small porcelain cups and drunk pure without any admixture. Tea taken in this way is extraordinarily refreshing. When in Japan, I have sometimes, after being engaged in the fatiguing, incessant but fascinating occupation of shopping, turned to the saleswoman serving me and said, *Ocha dozo oka san*, which means, 'Please give me a cup of your honorable tea, good lady,' at which request the tiny teapot has been immediately produced with many smiles and bows, and has yielded an astonishing number of small cups, water being continually added from the pretty chased iron kettle. After this 'restoration' shopping again became fascinating."

The tea ceremony in Japan is thus described:

"There is another kind of tea which is also drunk in Japan on the occasion of the unique and solemn Tea Ceremony. This ceremony, which has become a national and tenaciously held custom, was invented by a great chieftain called Hideyoshi, in the early part of the sixteenth century, with the object of teaching his turbulent barons to be courteous, self controlled and silent. At the Tea Ceremony, the details of which are long, elaborate and definitely arranged, a fine green tea which has been ground into powder is brewed in a regular and ceremonious manner by an officer of the household, called the Cha-nou. The tea powder is stirred with a whisk in hot water in an antique bowl. This bowl of tea is handed round to the

guests seated on their heels on the matting, and is drunk, tea-dust and all, in solemn silence, the bowl being returned to the Cha-nou with forehead bowed to the ground."

But the book must be read to be best appreciated. It is well illustrated and neatly printed.

The American Year-Book of Medicine and Surgery; being a yearly digest of Scientific Progress and Authoritative Opinion in all branches of Medicine and Surgery, drawn from Journals, Monographs and Text-books, of the leading American and Foreign Authors and Investigators. Collected and arranged with critical comments by J. M. Baldy, M.D., C. H. Burnett, M.D., Archibald Church, M.D., C. F. Clarke, M.D., J. Chalmers Da Costa, M.D., W. A. N. Dorland, M.D., V. P. Gibney, M.D., Homer W. Gibney, M.D., Henry A. Griffin, M.D., John Guitéras, M.D., C. A. Hamann, M.D., H. F. Hansell, M.D., W. A. Hardaway, M.D., T. M. Hardie, B.A., M.B., C. F. Hersman, M.D., B. C. Hirst, M.D., E. Fletcher Ingals, M.D., W. W. Keen, M.D., H. Leffman, M.D., V. H. Norrie, M.D., H. J. Patrick, M.D., Wm. Pepper, M.D., D. Riesman, M.D., Louis Starr, M.D., Alfred Stengel, M.D., G. N. Stewart, M.D., Thompson S. Westcott, M.D.; under the general editorial charge of GEORGE M. GOULD, M.D. Illustrated with numerous woodcuts in text and thirty-three half tone and colored plates. 8vo, cl., pp. 1183. Philadelphia: W. B. Saunders. 1896. [From W. T. Keener, Chicago.]

This work is one of the most elaborate digests, and while it does not assume to constitute a digest of the entire volume of medical literature of the year, it yet seeks to give a summary of what is new and valuable in the progress of the art during the period covered by it. "It is confidently believed," says the editor in his preface, "that no very significant fact has escaped review in the present pages: the material used has been not only the periodicals of the year, but also the more important monographs, text-books, etc. It has been an onerous task to all concerned to condense this enormous mass of matter so that we could offer the product in a single volume. The making of medical books has been so prolific that both the expense and the library space of the physician have become highly important considerations which we have kept steadily in view."

The editors have done their work well, and the book as finished is beyond praise. The publisher has spared no pains to produce a book with faultless typography and superb illustrations.

The Diseases of Children, Medical and Surgical. By HENRY ASHBY, M.D., F.R.C.P., and A. WRIGHT, B.A., M.B., F.R.C.S. Third edition, edited for American students by WILLIAM PERRY NORTHRUP, A.M., M.D. 8vo, cl., pp. 840. New York: Longmans, Greene & Co. 1896.

This is an elaborate book covering the entire field of pediatrics, both in medicine and surgery. The use of small type has enabled the authors to put a vast amount of material into the work without making it unduly bulky. There are twenty-seven chapters and 200 illustrations: these illustrations mostly from photographs of cases under the care of the authors. Little change has been made by the American editor, who thought best to leave the body of the book intact and insert his own views in the appendix. The formulæ were rewritten, except the old system of weights and measures, which are unchanged. This is one of the most useful books on the medical and surgical diseases of children that have recently appeared, and our readers will find it very satisfactory for reference. The teachings are sound and conservative.

Therapeutics of Infancy and Childhood. By A. JACOBI, M.D. Philadelphia: J. B. Lippincott Company. 8vo, cl., pp. 518. 1896.

Dr. Jacobi has succeeded in so impressing his personality upon the profession in this country, since he established the first American course of clinical instruction in pediatrics, thirty-five years ago, that his book will be welcomed with something like enthusiasm.

There are sixteen chapters, viz.: 1. Feeding of Sick Children. 2. Treatment of the Newly Born. 3. General Thera-

peutics. 4. Constitutional Diseases. 5. Infectious Diseases. 6. Diseases of the Digestive Organs. 7. Diseases of the Genito-urinary Organs. 8. Diseases of the Respiratory Organs. 9. Diseases of the Organs of Circulation. 10. Diseases of the Nervous System. 11. Diseases of the Skin. 12. Diseases of the Ear. 13. Diseases of the Eye. 14. Diseases of the Muscles. 15. Diseases of the Bones and Joints. 16. Addenda.

In the last chapter the topics discussed are Laborde's method of treating asphyxia, pernicious anemia, infantile scurvy, thyroid feeding, antitoxin and milk sterilization. The author's recommendations are wise and conservative, and will have that weight and authority which his long and useful life so well entitles him to expect.

A History of the Chronic Degenerative Diseases of the Central Nervous System. By THOMAS KIRKPATRICK MONRO, M.A., M.D. 8vo Cl. Glasgow: Alex. Macdougall, 1895.

This work is a republication of a series of papers first published in the *Glasgow Medical Journal* of last year. They consist of historical studies of a number of the chronic disorders that "depend upon primary degenerative changes in the structure of the central nervous system," including tabes, primary spastic paralysis, ataxic paraplegia, Friedrich's disease, progressive muscular atrophy, bulbar paralysis, ophthalmoplegia, the peroneal type of muscular atrophy, and multiple sclerosis. The author omits paresis and primary optic atrophy which he admits might also be included in this class considered from some points of view.

The historical study seems to have been quite well and thoroughly done and the discussion of the different questions that have arisen in regard to the various authors who have written on these disorders is fair and judicious. While the scope of the work might have been extended, even beyond what is indicated by the author, to fully include the class of affections considered, it is, as far as it attempts to give, a very creditable contribution to medical literature.

The Retrospect of Medicine. A Half-Yearly Journal containing a Retrospective View of every Discovery and Practical Improvement in the Medical Sciences. Edited by JAMES BRAITHWAITE, M.D., etc., assisted by E. F. TREVELYAN, M.D., etc. Volume cxii, July to December, 1895. Issued January, 1896. London: Simpkin, Marshall, Hamilton, Kent & Co.

The current volume of "Braithwaite" is an interesting one. In whatever department of medical literature one may be interested, he will here find much to instruct and entertain him. The selections are judicious and drawn from a wide field. American medical literature seems fully represented.

Chemically Pure Hypophosphites and Syrup of Hydriodic Acid. By R. W. GARDNER. New York, 1895. Mailed on application.

This book is a complete dissertation on the uses of these drugs, and contains matter of considerable importance to the general practitioner.

PUBLIC HEALTH.

Municipal Cold Storage.—The municipality of Genoa, Italy, has constructed a cold storage plant at an expense of 60,000 lire, which nets 10,000 lire to the city every year. It is principally for meat which is received from America direct, according to Prof. Perroucito's report on the subject to the Society of Hygiene at Turin.

Tubercle Bacilli in Milk. Obermüller (*Hygien. Rundschau*, 1895, No. 19) undertook to examine milk purchased from dealers, for the presence of tubercle bacilli, because it seemed probable that, in view of the large number of tuberculous cows, bacilli would often be present in milk. He therefore injected into the peritoneal cavity of forty guinea pigs 2 to 2½ c.c. of milk. Of these forty, three died from extensive tuberculosis of the peritoneum. In a second series of experiments the

author used the sediment of centrifugalized milk mixed with the cream of the same milk, because it was learned from control experiments, that bacilli in centrifugalized milk not only reach the sediment, but also the layer of cream. With this mixture he injected intraperitoneally twenty-six guinea pigs, giving each 1 to 1.5 c.c. and of these ten, or 38 per cent., died from tuberculosis. Inasmuch as boiling as well as pasteurization of milk in reality are only palliative measures, he advocates strongly the weeding out of tuberculous animals after testing with tuberculin.

Sanitary Homes for the Working Classes.—The *Revista de Higiene*, of Santiago, Chile, brings us an important article on the subject of sanitary homes for the working classes. The author, after a masterly historic summary, concludes that it is a matter in which neither the government nor the municipality should take the initiative, as that is sure to lead to abuses, but they should encourage and foster private enterprise by legislation, remitting taxes, etc. This would make the enterprise a safe and profitable investment for associations, which, experience shows, accomplish more than individuals. He draws a terrible picture of the present homes of this class in Santiago, where hygiene is only just beginning to receive attention among the well-to-do, and the poor are crowded together in small, low, damp huts, on unpaved streets, without a single opening except the entrance from the street, and with the sewage in open ditches, often stagnant. The floor is frequently below the level of the street, which means constant infiltration of dampness. The huts called *ranchos* are still worse, as the green materials of which they are composed are always moist and decaying. A slight improvement are the *courventillos*, which are the usual round houses without windows or doors except the one entrance from the street, but they open on a private street which serves as a common court where all the cooking and washing are done outside of the house. Nearly every hut contains, besides the family, one or more domestic animals. The author ascribes the unusual amount of drunkenness in Santiago to these uninviting homes. There were 24,034 arrests for this cause alone in 1893, while in all London there were only 30,000, and in Valparaiso 12,828. He admits that Santiago is behind other cities in the country in sanitary living, although location and climate are exceptionally favorable. If it were not for the latter, with its cool nights all the year around, epidemics would certainly prevail all the time, instead of being limited to August, September and October.

Health Reports.—The following health reports have been received in the office of the Supervising Surgeon-General Marine-Hospital Service:

SMALLPOX—UNITED STATES.

Arizona: Nogales, January 13, 1 case.
Arkansas: Mayflower, Faulkner County, January 4 to 13, 2 cases; (near) Conway, Faulkner County, January 4 to 13, 6 cases; Widener, January 4 to 13, 1 case; Crittenden County, January 19, 24 cases, 5 deaths.
Illinois: Chicago, December 1 to 31, 2 deaths; Cairo, January 14, 2 deaths.
Indiana: Michigan City, year 1895, 1 death.
Louisiana: New Orleans, January 4 to 11, 7 cases, 1 death.
Michigan: Detroit, January 4 to 18, 2 cases.
Missouri: Birds Point, January 14, smallpox reported present.
Tennessee: Memphis, January 1 to 18, 6 cases.

SMALLPOX—FOREIGN.

Cairo, December 7 to 16, 1 death.
Corunna, December 1 to 31, 5 deaths.
Dublin, December 28 to January 4, 1 case.
Havana, January 2 to 9, 2 deaths.
Madrid, December 24 to 31, 11 deaths.
Montevideo, December 7 to 14, 2 cases.
Moscow, December 14 to 21, 1 case.
Odessa, December 21 to 28, 8 cases.
Prague, December 7 to 14, 26 cases; December 24 to 28, 6 cases.
Rio de Janeiro, December 7 to 21, 72 deaths.

St. Petersburg, December 21 to 28, 7 cases, 2 deaths.
Trieste, December 7 to 28, 2 cases, 1 death.
Warsaw, December 7 to 21, 4 deaths.

CHOLERA—FOREIGN.

Austria-Hungary, December 17 to 22, 5 cases, 2 deaths.
Egypt: Cairo, December 9 to 16, 1 death; Borachia, December 15 to 16, 2 cases; Damietta, December 12, 1 death; Faras-kour, December 11 to 12, 2 cases, 2 deaths; Hehya, December 13, 1 death; Kafr-el-Battikh, December 12 to 17, 28 cases, 15 deaths; Mansurah, December 17, 1 case, 1 death; Zagazig, December 15 to 18, 5 cases, 2 deaths.

Russia: Kiev (government), November 17 to December 7, 219 cases, 85 deaths; Orlov (government), November 3 to December 7, 17 cases, 6 deaths; St. Petersburg (city), November 30 to December 7, 73 cases, 46 deaths; December 21 to 28, 56 cases, 48 deaths; St. Petersburg (government), November 17 to December 7, 21 cases, 2 deaths; Volhynia (government), November 17 to 30, 442 cases, 184 deaths.

India: Bombay, December 10 to 17, 2 deaths; Calcutta, December 1 to 7, 59 deaths.

YELLOW FEVER—FOREIGN.

Cuba: Cienfuegos, December 29 to January 5, 3 deaths; Sagua la Grande, December 28 to January 4, 12 cases, 5 deaths; Santiago de Cuba, December 28 to January 4, 15 deaths.
Brazil: Rio de Janeiro, December 7 to 21, 55 deaths.

NECROLOGY.

DR. L. CH. BOISLINIERE died January 13, aged 80. His death takes away one of the most honored of the medical profession of St. Louis, where he lived and worked for almost fifty years. He was born in the West Indies in 1816. He went to France to continue his education and graduated in law at the University of Paris. He soon began to show a preference for medicine, and became a member of the Anthropological Society of Paris. His connection with the society was maintained until his death. On returning to America in 1846, for some time he made his home in Louisville, Ky., then came to St. Louis and graduated from the St. Louis Medical College in the class of 1848. In 1870 he succeeded Dr. M. M. Pallen as Professor of Obstetrics in his Alma Mater; at the time of his death he was Professor Emeritus. Dr. Boisliniere will be remembered for his unflinching kindness, his wide learning and his enduring influence on the profession. Among his earlier achievements was his success in bringing the Sisters of St. Anne to St. Louis, who established here the first lying-in hospital west of the Alleghany mountains. At a called meeting of physicians held at the Missouri Medical College, Dr. W. G. Moore, president of the St. Louis Medical Society, presented resolutions which embodied an eloquent tribute to the memory of Dr. Boisliniere. Addresses in eulogy of the departed physician were made by Drs. J. K. Bauduy, I. N. Love, E. F. Smith, W. A. Hardaway, P. S. O'Reilly, J. P. Bryson, P. G. Robinson, W. B. Dorsett and others. Dr. Hardaway spoke in favor of erecting some suitable memorial in honor of the deceased, and Dr. Moore appointed Drs. Hardaway, Dorsett, Bauduy and Bryson a committee to report upon this project.

JOHN FORD BARBOUR, M.D., of Louisville, Ky., died January 15. The news of the death of Dr. Barbour came as a great shock to his many friends, as his illness was unknown except to a few. Several weeks ago he contracted a pleurisy, but was not thought to be seriously ill until a day or so before his death. Dr. Barbour was born in Lexington, Mo., May 25, 1861, and was the son of Prof. Louis G. Barbour, D.D., LL.D., who is professor of mathematics at Central University, at Richmond, Ky. Dr. Barbour was a graduate of Central University and afterward studied medicine at the Hospital College of Medicine, this city, graduating at University of New York, Medical Department, in 1881. He returned to Louisville and began the practice of his profession in 1884, and soon worked his way up to a large practice. Dr. Barbour paid special attention to diseases of the nervous system and of the stomach, and

some of his most valuable contributions to medical literature were upon these subjects, among which may be mentioned "The Present Status of Craniectomy," a paper read before the Louisville Academy of Medicine; "Neurasthenia," a paper presented at a recent meeting of the Louisville Medico-Chirurgical Society, and "The Modern Treatment of Diseases of the Stomach," read before the Louisville Clinical Society. Had he turned his attention to music instead of medicine he would have made a great reputation as a composer and performer. Some of his compositions have been commended very highly by critics, and he was an excellent pianist. He was the editor of the *New Albany Medical Herald*; a member of the Kentucky State Medical Society; Louisville Academy of Medicine; Louisville Medico-Chirurgical and Louisville Clinical Societies, and also a valued member of the Bluestocking Club, a prominent local literary society. After his return from New York he became attached to the staff of the Louisville Hospital College of medicine as lecturer on diseases of the nervous system, soon working up a large clinic; he was afterward assistant to the chair of practice, and from 1889 to 1892, professor of clinical medicine in the same school. Dr. Barbour was a brother of Dr. Philip F. Barbour, Professor of Chemistry in the Hospital College of Medicine; and cousin of Dr. P. C. S. Barbour, Superintendent of the Louisville City Hospital. He was also a member of the visiting staff of this institution. His remains were interred at Danville, Ky.

STEPHEN VAN RENSSELAER BOGERT, M.D., of Sailors' Snug Harbor, Staten Island, N. Y., died January 10, in the ninety-second year of his age. He was a native of Albany, N. Y., and graduated in 1825, from the College of Physicians and Surgeons at Fairfield, Western New York. He was about forty years the resident physician at the Sailors' Snug Harbor, and was consulting physician to the St. Nicholas Society of New York. About twelve years ago he retired from active practice. His interment took place in the Moravian Cemetery of Staten Island. His son, Edward S. Bogert, is a medical director of the United States Navy.

PLO RENGIFO, M.D., formerly editor of the *Revista Medica*, of Bogota, died at Panama, Colombia, January 14, from a cerebral hemorrhage. He was a graduate in medicine from the University of St. Andrews, Scotland, and studied in medical clinics of Berlin, Paris and Vienna. He practiced his profession in New York City for ten or more years and afterward was for a time located at Lima in Peru. He was a scholarly man, of fine attainments and of great force of character. His brother, Gen. Julio Rengifo, is well known in diplomatic circles at Washington.

C. V. BEEBE, M.D., of Superior, Wis., January 8, aged 54.
— Abraham Losier, M.D., of New York, January 14.
— Sarah J. Fearing, M.D., of Denver, Colo., January 11.
— Orin Goodrich, M.D., of Troy, N. Y., December 23, aged 88 years.
— E. P. Austin, M.D., of Noblesville, Ind., December 22, aged 89.

MISCELLANY.

Two Insane Asylums for Colored People. Laws were in 1895 passed in Tennessee providing for the erection of two insane asylums for the insane colored people of West and East Tennessee respectively. One is to be on the grounds of the West Tennessee Insane Asylum near Bolivar, in Hardeman County; the other to be located upon the grounds of the Hospital for the Insane at Lyon's View, Knox County, Tennessee. Admission to each is to be apportioned to the counties within its part of the State according to population as shown by the latest federal census. The county physician, county judge or chairman of the county court has authority to send to the former institution. Pay patients shall be admitted to the latter, which is under control of the trustees of the institution on the grounds on which it is located.

Disposition of Criminals Recovering Reason.—Chapter 103 of the Laws of Wyoming enacted in 1895 provides for the custody and treatment, at such place or places as the board of charities and reform shall provide or prescribe, of persons of unsound mind who have been accused or convicted of criminal offenses. But section 5 thereof provides that if any such person or patient so confined in any hospital or asylum or place designated by said board shall recover his or her reason, he or she shall be returned to the penitentiary, county jail or other place of confinement or imprisonment where such person was confined at the time of the inquiry, trial or proceeding had to determine his or her sanity, or insanity, there to be tried or to serve out or undergo his or her term of imprisonment if any part thereof remains, as the nature of the case shall require.

A Philanthropic Physician Rewarded.—The following item from a religious weekly refers to a medical man of London who has long been engaged in caring for orphans and city waifs, his work in that direction running up into the thousands of boys and girls rescued and provided with homes. Dr. T. J. Barnardo has recently recovered from a severe illness, and his friends took the occasion of his return to duty to give him an evidence of their estimation of his work. An evidence of the extent of this work will be seen in the fact that he has to raise over \$700 per day. The item reads as follows: "The work of Dr. Barnardo in caring for the destitute children of London has received public acknowledgment. At a reception at Exeter Hall he was presented with an illuminated address and a check worth \$17,085. This was a personal gift apart from the children's support. Dr. Barnardo now has eighty-four homes in which 5,000 destitute children are clothed, fed and educated. The expenses are over \$700 per day."

Albany Medical Alumni Dine. The first annual dinner of the newly-formed Albany Medical College Alumni Association of Greater New York was given January 16. The association was organized December last, and has a membership of nearly seventy-five. The dinner was served in the octagonal banquet hall of the Hotel Savoy, and about fifty members assembled at the first festive meeting of the association. The President, Dr. John W. Warner, occupied the central seat of the table of honor. In company with him were the Rev. Dr. John E. Bushnell, Prof. Albert Van der Veer and Prof. Samuel B. Ward, of the faculty of the college; the Rev. Dr. Andrew V. Raymond, President of Union College, and Dr. Edward Hall. Among the guests were Assistant District-Attorney John F. McIntyre, John P. Faure, Commissioner of the Public Charities; Prof. William H. Thompson, ex-Congressman John S. Wise, of Virginia; Dr. Maurice J. Lewis, Secretary of the State Board of Medical Examiners, and St. Clair McKelway. There were also present the following officers of the alumni: Dr. Horace Macy Hanks, Vice-President; Dr. Warren C. Spalding, Secretary; Dr. Robert F. Macfarlane, Assistant Secretary; Dr. Allen Fitch, Treasurer; Dr. John A. Cutter, Dr. Robert E. Fivey, Dr. L. N. Lanehart, of Hempstead, N. Y., and Dr. Henry F. Muller, of Brooklyn, Governors.

Sale of Intoxicating Medicine.—A Mississippi judge not long since decided that if a certain duly licensed druggist sold essence of ginger, which, when diluted with water and drank to excess, would produce intoxication, he must be convicted of selling intoxicating liquors, without regard to his motive, its being a medicine, or the fact that as sold it could not be used as a beverage. As a consequence, apparently, the druggist was convicted of this violation of the law. But, Nov. 4, 1895, the supreme court of Mississippi reversed the judgment of the lower court. (Bertrand vs. State.) It says the test question in the case was whether the essence of tincture of ginger referred to was a medicine, sold as such in good faith, and not as a beverage, or whether it was a sham preparation, disguised as medicine, really an intoxicating liquor sold as a beverage. Evi-

dence on this line, offered by the druggist, tending to show the character of the preparation and his good faith, it is held, should have been admitted. Likewise, he is declared to have had the right to have had the jury instructed that if they believed from the evidence that he, the accused, sold tincture of Jamaica ginger as a medicine, in good faith, and believed further from the evidence that the same was prepared by the directions of the United States dispensatory, and that the same was recognized by the medical profession of the United States, they should acquit.

Tennessee Restricts Holders of Inquests. The laws of Tennessee were amended in 1895 to the effect that no inquest shall be held by the coroner or any justice of the peace over the dead body of any person or persons, until an affidavit in writing is made and signed by two or more reliable persons, averring the death of said person or persons, and that there is good reason to believe that such person or persons came to his, her or their death by unlawful violence at the hands of some other person or persons; and without such affidavit in writing, such coroner or justice shall have no jurisdiction to hold an inquest over the dead body of any person or persons whomsoever; and all proceedings without such affidavit shall be utterly void and useless unless these provisions are literally, rigidly and strictly complied with, and the affidavit filed with the papers, and the coroner or justice of the peace shall receive no fees or compensation for holding the inquest. If any person or persons shall falsely, willfully and corruptly swear out such affidavit as above provided for, such person or persons so swearing shall be deemed guilty of perjury, and punished as now provided for by law for said offense; and in addition to the penalty now provided by law for perjury, they shall be taxed with all the costs incidental to said inquisition, based upon said false and corrupt affidavit.

A Collective Inquiry Regarding Schlatter's "Cures." The editor of *Voice* has been in correspondence with the medical men and others of Denver for the purpose of getting statements as to the alleged cures of Michael Schlatter. Three physicians reply that there were no cures known to them. Another replies that no organic disease was cured, such as affections of the eyes and ears, but one woman received benefit. This patient appeared to be on the point of losing her mind from melancholic tendencies. She was extremely nervous, morose and could not sleep, but after being treated by the Healer she recovered entirely, slept well and became quite rational. He admits that Schlatter did for her what he could not do, and adds: "The majority of humanity wants something or some one to lean upon. Schlatter's strong mind furnished that something and many were greatly benefited in mind. He did good, and I am glad he came." One of the letters was from Dr. Charles N. Hart, president of the State Medical Society. He says he knows of several cures for which he is willing to give Schlatter credit. One was that of an aged woman who could not sleep and could get no relief from her physician. After she saw Schlatter she slept well and has slept well ever since. All the cases of cure Dr. Hart knows of were cases of nervousness, and it is his opinion that Schlatter helped about 1 per cent. of all those that came to him. That would be, as he estimates it, fifteen to twenty daily. In Dr. Hart's opinion he did no harm, but considerable good in helping a class of cases which the average physician can not help; and he does not doubt that an explanation can be found on natural grounds for all the cures of which Schlatter was the agent.

Weight to be Given Expert Testimony. The trial judge instructed the jury in the case of *People vs. Seaman*, that: "Some expert testimony has been given in this case, but its value depends upon the circumstances, and of these circumstances the jury must be the judge. The jury must determine the weight to be credited to it, but in all cases the testimony of experts is

to be received and weighed with great caution. The evidence of a witness who is brought upon the stand to support a theory by his opinion is testimony exposed to a reasonable degree of suspicion, which there is great reason to believe is in many instances the result of employment and his bias arising out of it. In many cases, it is to be feared, by giving too much weight to testimony of experts, juries have been induced to render unwarrantable verdicts, discreditable to the administration of justice, as well as exceedingly detrimental to public interests." This instruction, the supreme court of Michigan holds, Dec. 10, 1895, was clearly erroneous. An expert witness, it says, is to be judged from the same standpoint as any other witness. It was for the jury, and not for the court, to determine the weight to be given to the testimony. Expert testimony is not always the most reliable, but it is often indispensable. Its infirmity arises largely from its character. Comparatively, it has been held to have little value. It does not follow, because experts differ, that the testimony should be said to be suspicious. Lay witnesses differ materially in their testimony as to conversations and occurrences. Judges, lawyers and juries differ in their conclusions from a given state of facts. It can not be assumed as a matter of law that this testimony is open to suspicion for the reason that experts are employed, and are necessarily biased by such employment. In this case, for example, the evidence as to cause of death was circumstantial. And it must be conceded, continues the court, that the experts who held an autopsy for the very purpose of determining the cause were better qualified to determine what symptoms usually precede a miscarriage, and what are the ordinary causes which produce it, and what the condition of the body indicated upon examination made, than is the ordinary layman. The other circumstances of the case bearing upon the death cause and the defendant's guilt were for the jury, and it was their province to determine those questions from all the facts and circumstances, and to disregard the opinion evidence as to the cause of death, if, in their judgment, the other testimony warranted that conclusion.

Minnesota Changes in Regulation of Practice of Medicine.—The Minnesota legislature in 1895 amended the law of that State relating to the practice of medicine and the licensing of physicians and surgeons in several important respects. First, it provided that three, instead of two, of the nine members of the State Board of Medical Examiners shall be "homoeopathic" physicians. Then it changed the time for the summer meeting of the board for holding examinations from the first Tuesday in July to June. In the third place, it declared that it shall be unlawful for any person to practice medicine in that State without a license from said board, or without having filed with the secretary of said board an affidavit setting forth the times and places in which he or she has practiced medicine within the State prior to the passage of this law (the act 1887, here amended). Any person in continuous practice in the State since June 1, 1887, not licensed under the provisions of chapter 125 of general laws of 1883, may become a licensed practitioner by submitting to the board of medical examiners a diploma from a recognized college of medicine, or by undergoing an individual examination at a regular examination prescribed by the act now in force. The fee for such license shall be \$10. The previous requirement that candidates for examination present evidence of having attended three courses of lectures of at least six months each, is changed to "three full courses of lectures at a medical college, recognized by the State Board of Medical Examiners, of at least twenty-six weeks each; no two courses being within the same year." After January 1, 1899, it shall be necessary for all persons commencing the practice of medicine and surgery to submit to an examination and present evidence of having attended four full courses of lectures at a medical college, recognized by the

State Board of Medical Examiners, of at least twenty-six weeks each; no two courses being in the same year. All examination papers on subjects requiring treatment peculiar to any school of medicine shall be examined and their sufficiency passed upon by the members of said board belonging to such school, if such there be, and their recommendation as to the proficiency of such candidate in those particular subjects shall be deemed final by said board.

The Leidy Memorial Fellowship in Anatomy.—The following circular has been issued:

It has seemed unjust to many that there is no suitable memorial to perpetuate the name of Joseph Leidy, the great scientist and teacher. A committee has therefore been organized from among his old students to raise whatever money may be made for the accomplishment of this object.

There is no idea more suitable, no testimonial more practical, none which would appeal more to the judgment of the great investigator himself, than the establishment of a Fellowship in Anatomy, the great division of medicine which he loved so well. As the University of Pennsylvania was the scene of the greater part of his labors, the committee has thought it best to establish the Fellowship in that Institution.

The creation of the Fellowship will not only perpetuate the name of Leidy, but will enable some practical working Anatomist to carry on original work in the University, and to utilize the vast collection of material which is deposited in the Wistar Museum.

Thirty thousand dollars will put such a Fellowship on a permanent working basis, it being intended that the income from this sum should be paid to the Fellow, thus enabling him to pursue his studies with the assurance that his daily wants will be provided for. We appeal to you, therefore, as lovers and admirers of the gentle, humane scientist whose achievements have made his name familiar on two continents, to aid us by subscribing to this Fund.

The movement is a general one, and if you desire further information in regard to the purposes of this memorial, and the regulations which will govern it, we will be glad to communicate with you.

Communications and remittances should be addressed to the secretary and treasurer.

Committee: Dr. Wm. Campbell Posey, Chairman, Dr. Joseph Leidy, Dr. Joseph P. Tunis, Dr. Charles H. Frazier, Dr. J. Howe Adams, Secretary and Treasurer, 1523 Locust Street. Advisory Committee: Dr. S. Wier Mitchell, Dr. J. M. DaCosta, Dr. John Ashlurst, Jr., Dr. George A. Piersol, Gen. Isaac J. Wistar, Mr. C. C. Harrison, Provost of the U. of Pa. Philadelphia, Dec. 26, 1895.

Practical Notes.

Hidrosis At a recent meeting of the Berlin Dermatological Association formalin was recommended in the treatment of hidrosis, in a 0.10 to 0.20 per cent. solution; as also a mixture of formalin and tannin which has proved very successful in severe cases of hidrosis and bromhidrosis.

Lip Reading for Deaf Mutes by Aid of Photographs.—Deaf mutes are taught to understand spoken language by watching the movements of the lips and facial muscles. Dr. Gutzmann has recently secured a series of photographs showing these movements and mounted them in a gyroscope, when the words spoken were immediately recognized by the mutes. The *Deutsche med. Woch.* devotes considerable space to Gutzmann's success, which is sure to prove of the greatest assistance in teaching the deaf to understand spoken words.

Typhoid Bacilli not Transmitted from Mother to Fetus.—A case was described at a recent meeting of the Medical Association at Pavia, Italy, where a woman suffering from a severe case of typhoid fever was delivered of a five-months fetus, which was absolutely free from typhoid bacilli as deter-

mined by the most exhaustive tests. The transmission of disease from mother to fetus is not therefore inevitable, and may depend on special contingencies, such as placental hemorrhage. —*Gaz. degli Osp. e delle Clin.*

Stenosis of Pylorus.—The *Gaz. degli Osp. e Clin.* reports an operation of gastro-enterostomy for severe cicatricial stenosis of the pylorus at Vetralla, last March. The case required a large opening. Catgut and silk were both used. In fifteen days after operation, patient (a laboring man, age 45) was eating the richest diet the hospital afforded without inconvenience, and when he left, sixty days after operation, he was entirely restored to his normal health and had gained many pounds in weight. He resumed his ordinary work and has remained since in robust health. De Mattoli was the surgeon in charge of the case.

Sterilization of Catgut. The old problem of sterilizing catgut came up again at a recent meeting of the Berlin Medical Association and the importance of sterilizing it insisted upon, as it is in the highest degree infective. Boiling water and sublimate are of course out of the question; but De Saul announced that he had succeeded in thoroughly disinfecting the catgut with boiling alcohol (ethyl alcohol), without injury to it. Carbolic acid mixed with it did not assist the sterilizing process until water was added, when the sterilizing strength was very much enhanced. Dr. Saul showed a small contrivance by which the process was most simply and effectively done. He announces the exact formula as 85 parts alcohol, 5 parts carbolic acid and 10 parts water. In the discussion that followed the objection was made that ethyl alcohol will not mix with water. —*Deutsch. med. Woch.*

Society Notes.

THE CLINTON COUNTY (IOWA) MEDICAL SOCIETY, January 7, appointed the following delegates to attend the Atlanta meeting of the AMERICAN MEDICAL ASSOCIATION: Drs. D. Langan, P. J. Farnsworth, H. F. Farnsworth and G. Hofstetter.

THE MEDICAL COUNCIL, of Syracuse N. Y., had its regular monthly meeting January 7. Dr. Alfred Mercer, the retiring president, read an able paper on "The Decline of Blood Letting and its Use in Pneumonia." After the reading a general discussion on the subject was participated in by Drs. Henry D. Didama, A. J. Dallas, E. R. Maxson, E. Vandewarker, J. L. Heffron and others. The subject proved to be an interesting one and the practice of bleeding was approved by most of the speakers in dealing with many cases of pneumonia under certain conditions.

Hospital Notes.

A HOSPITAL UNDER LAY REGIME: THIRTY YEARS' WORK GOES FOR NOUGHT.—At the Manhattan Hospital and Dispensary, New York City, thirty members of the Board of Directors have resigned because of the withdrawal from the institution of Dr. Rodenstein, its founder, and the Chief of its Medical Board. The trouble is said to be the result of an attempt by the matron to obtain and keep the upper hand. According to the *New York Herald*, Dr. Rodenstein, at a recent meeting of the Board of Managers, was deprived of the honorary title he had held for thirty years of Chief of the Medical Board. "It was decided that a member of the Medical Board was not eligible for membership in the Board of Managers, which was another rap at the doctor. This so incensed Dr. Rodenstein that he forwarded his resignation to the Board. Thirty of the members of the Board of Managers and Ladies' Association, on learning of the doctor's resignation, tendered theirs also. The hospital was started thirty-four years ago as a dispensary by Dr. Rodenstein, who has contributed \$12,000 to its support and presented it with the lots on which the hospital stands. J. Hood Wright helped build a large building. The name of the hospital was changed last October to the J. Hood Wright Memorial Hospital, at the request of Mrs. Wright, who pays \$6,000 a year of the \$25,000 that it takes to support the institution."

THE DIRECTORS OF THE NEW BRITAIN GENERAL HOSPITAL have purchased a site for that institution at a cost of \$20,000. —Theodore Sargent, M.D., of Garrett, Ind., has been appointed surgeon of the La Fayette, Ind., Soldier's Home.

Detroit Notes.

THE DETROIT MEDICAL and Library Association at its regular meeting Monday, January 13, was entertained by Dr. W. R. Chittick who read a paper entitled, "The Effects of Heart Strain on the Tricuspid Valves."

AT THE REGULAR MEETING of the Wayne County Medical Society held January 16, Dr. Arthur Bennett read a paper on "Permanent Permeability of the Foramen Ovale," and exhibited a patient.

HEALTH OFFICE REPORT for week ending Jan. 18, 1896. Deaths, under five years 41, total 91. Births, male 42, female 51, total 93. Contagious diseases: Diphtheria, last report 28, new cases 17, recovered 16, died 2, now sick 27. Scarlet fever, last report 18, new cases 9, recovered 8, died none, now sick 19. Smallpox, last report 2, new cases 2, recovered 1, died none, now sick 3. Measles, last report 1, new cases none, recovered 1, died none, now sick none.

THE BOARD OF TRUSTEES of Harper Hospital at their annual meeting appointed the following Medical Board for 1896: J. H. Carstens, Chief of Staff. Consulting surgeons: Theo. A. McGraw, Donald Maclean. Attending surgeons: Daniel LaFerte, H. O. Walker, J. K. Gailey, E. T. Tappey. Consulting physicians: C. A. Devendorf, Chas. Douglass. Attending physicians: Geo. Duffield, J. J. Mulheron, W. R. Chittick, D. S. Campbell. Consulting oculists: L. Connor, Geo. E. Frothingham. Attending oculists: Geo. E. Frothingham, Jr., Don. M. Campbell. Consulting neurologist: David Inglis. Attending neurologists: J. E. Emerson, C. W. Hitchcock. Dermatologist: A. E. Carrier. Laryngologist: E. L. Shurly. Gynecologists: H. W. Longyear, J. H. Carstens, W. P. Manton, Helen F. Warner. Microscopist: E. H. Sargent. Consulting pathologist: Henneage Gibbs. Assistant surgeons: W. G. Henry, F. B. Tibbals. Pathologist and curator: P. M. Hickey. Junior surgeon: Angus McLean. House physicians: C. W. Barrett, B. R. Shurly, A. D. McLean, Henry H. Kuhn. Polyclinic staff: Director—H. R. Varney: General medicine—Hedley Williamson, E. G. Knill: Surgical diseases—L. E. Schell, R. T. Farrand: Nose and throat—W. S. Anderson, H. A. McEachren: Eye and ear—G. L. Renaud, George Suttie: Diseases of women—Emma D. Cook, Anna J. Clapperton, John N. Bell: Nervous diseases—W. J. Senkler: Skin diseases—H. R. Varney.

Louisville Notes.

ERUPTIVE HOSPITAL. In accordance with a resolution passed at a recent meeting of the general council, the resignation of the Roman Catholic Sisters in charge of the Eruptive Hospital has been requested and received. The Sisters have been in charge of the hospital for five years. The Board of Public Safety has appointed Dr. C. T. Pope as superintendent, with a salary of \$75 a month. The superintendent is empowered to hire competent nurses when any cases of contagious disease are admitted.

CITY PHYSICIAN.—Dr. Hugh McCullough, the late coroner of Jefferson County, has just been appointed by the Board of Public Safety as City Physician to the eastern district, vice Dr. Forst resigned. The position pays about \$75 a month.

CENTRAL KENTUCKY MEDICAL SOCIETY. This Society held its annual meeting in Danville, Ky., on January 15 and 16. The following officers were elected: President, Dr. James B. Kinnaird, of Lancaster; Vice-president, Dr. G. E. Davis, of Salvisa; Treasurer, Dr. W. D. Powell, of Harrodsburg; Secretary, Dr. Steele Bailey, of Stanford. The next meeting will be held in Stanford the first week in April. Dr. T. C. Evans, of Louisville, was in attendance and read a paper on "Cancer of the Tonsils."

GWYNN.—"Doctor" Gwynn has been arrested in Bardstown, Ky., upon the instigation of Drs. Hill and Blincoe, for practicing without a license or diploma. He has been arrested before on the same charge, and was practicing under the name of Guyann. He was committed to jail in default of bail of \$100.

DR. RAMSEY.—Dr. M. C. Ramsey, formerly of this city, died

at his home in Lexington, Ky. He was born near Madison, Ind. seventy-two years ago. In early life he was a practicing physician, but deciding to adopt a commercial career, he came to this city in 1853, and was for twenty-six years one of the leading jewelers. Later he moved to Lexington, Ky. where he resided until his death. His remains were brought here for burial.

DR. JESSEE. Dr. John Jessee has been elected Professor of Physiology in the Central Normal College at Waddy, Ky. The appointment is a well-merited one.

DEATH REPORT. The condensed statement of mortality prepared by Health Officer White, for the past week, shows a total of 50 deaths, being 10 less than the previous week. Pneumonia caused 8 deaths.

CONTAGIOUS DISEASES. The ordinance looking to the prevention of contagious diseases having been passed by the general council and approved by the late mayor, Henry S. Tyler, is now in effect, but as yet all physicians of the city are not cognizant of it. The law requires that the notice should be sent to the health officer, over the signature of the physician attending. The health officer complains that physicians notify him over the telephone which is contrary to the law.

BARBOUR. Dr. John Ford Barbour died at his residence in this city on January 16, of acute pneumonia, after an illness of four days.

Cincinnati Notes.

THE MORTALITY report for the past week gives: Croup 2, diphtheria 5, measles 7, typhoid fever 4, other zymotic diseases 8, cancer 2, phthisis 9, other constitutional diseases 2, apoplexy 2, Bright's disease 2, bronchitis 6, convulsions 3, meningitis 7, peritonitis 2, pneumonia 17, other local diseases 28, violence 4, under 1 year 15; all causes 117; annual rate per 1,000 18.10. Corresponding week 1894, 125; 1893, 134.

FOUR CASES of measles in adults presented themselves at the Cincinnati Hospital last week.

THE PRESBYTERIAN HOSPITAL for Women and Children has had a donation of \$20,000, from Mrs. Alexander McDonald to wipe out the existing debt.

DR. LINCOLN MUSSEY was married on the 7th to Miss Judith Culvert of Cincinnati.

FRANK AUZERNE has been appointed steward of the First Regiment O. N. G., to succeed Dr. Otto Reum, who has located in Los Angeles, Cal., on account of poor health. Mr. Auzerne has served two enlistments in the U. S. Army as Hospital Steward.

DR. JOHN C. OLIVER has been appointed a member of the Board of Examining Surgeons of the police department vice Dr. N. P. Dandridge resigned.

JAMES SHERLOCK has been appointed superintendent of the Branch Hospital or "Pest House."

DR. MARSHALL H. KEY has located in the Nean building, and also announces the opening of the Highland Sanitarium.

DR. FERD. H. HUELSMANN met with a serious accident last week by falling through an open trap door leading to a drug store cellar. He sustained a broken nose, several severe bruises of the head and internal injuries.

THE REPORT of the Cincinnati Hospital shows that the recent smallpox epidemic necessitated the expense of \$449.49 in improvements and \$3,938.37 for the care of patients, cleansing and disinfecting the buildings of the Branch Hospital. There were 143 cases cared for. The expenses of the hospital for the year were \$109,359.96.

THE APPROPRIATIONS of the State for the past year were as follows: Board of Health, \$8,000. Dairy and Food Commission \$25,100. State Hospitals: Athens, \$142,585.78, Cleveland \$157,350. Columbus \$181,100. Dayton \$128,200. Longview \$35,000. Massillon \$50,000. Toledo \$174,650. Epileptic hospital at Gallipolis \$138,100.

A CURIOUS CASE was discovered at the morgue last week by

the coroner, who being called there to investigate a case of an infant which had died under somewhat peculiar circumstances within twenty-four hours after birth, found that the upper jaw contained a completely developed set of teeth.

THE STATE BOARD of Health are endeavoring to obtain a better system of vital statistics, and their annual report says: "No one knows the number of deaths or the number of births that occurred in Ohio during the past or any other year. Thousands die and thousands are born of whom no official record is made or can be obtained. Crime is made easy, the settlement of estates and legacies difficult, and a study of the causes of death and means for their removal impossible from the lack of such records."

Regarding smallpox it says: During the year there appeared, at Cincinnati, 143 cases; Cleveland, 17 cases; Bridgeport, 16 cases. It was also present at Toledo, Columbus, Mansfield, Lima, Martin's Ferry, Peace Township, Belmont County; Gallipolis Township, Gallia County; Deerfield, Wellington, Addyston, Westwood, Williamsport and Ridley."

SALEM, OHIO, has just had a smallpox scare.

THE CASES of smallpox at Martin's Ferry are all doing well and the quarantine has been raised.

DR. J. A. CULVER, the gold-medal graduate of the Ohio Medical College class of 1874 died December 20, from the excessive of morphin.

AT THE MEETING of the Academy of Medicine January 6, Dr. Julia W. Carpenter read a paper on the open-air treatment of pulmonary consumption. The amendments to the constitution were also brought up for final reading and were passed. The principle change being that, in the future, amendments to the constitution can be voted upon after the proposed change has been read three times with an interval between of not longer than two weeks instead of the requisite three months between the first reading and the voting as heretofore.

St. Louis Notes.

WEEKLY REPORT OF HEALTH OFFICE.—Total number of deaths for the week ending January 18, 187, compared with 189 for the preceding week, and 158 for the corresponding period of 1895. Births reported, 208.

CONTAGIOUS DISEASES.—Reported during the week ending January 18, diphtheria, 58 cases, 13 deaths; croup, 8 cases, 4 deaths; typhoid fever, 6 cases, 2 deaths; measles, 36 cases, 1 death; whooping cough, 3 cases, 1 death; scarlatina, 9 cases.

ST. LOUIS MEDICAL SOCIETY. At the regular meeting January 18, the announced scientific program consisted of a paper on "Infiltration Anesthesia" by Dr. Bransford Lewis.

BURT G. WILDER, of Cornell University, gave a lecture Wednesday evening, January 15, at the St. Louis Medical College on the occipito-parietal fissure: on Thursday he addressed the students of the Marion-Sims College of Medicine on the utility of dissection of the lower animals as an introduction to the study of human anatomy.

THE STATE BOARD OF PHARMACY held its examination on January 13 and 14. Ninety-one candidates presented themselves and thirty seven passed.

THE STATE BOARD OF HEALTH and the medical colleges have furnished the most fruitful source of medical gossip during the week. At the meeting of the Board on the 6th inst., the matriculates of all the medical schools of the State were passed upon and measured by the rule of the Board requiring an increased standard of preliminary education. The reports that have since become current have caused in some instances freely expressed indignation, and charges of jealousy and favoritism have been openly reported. In all instances where students were found deficient under the sworn statement of the faculty the students, as well as the faculty, were notified that they had failed to come up to the requirements of the Board, but that they could present reasons to the Board why their names should be continued on the college list. The following gives a

list, approximately correct, of all the matriculates submitted to the Board, with number of those rejected;

Colleges.	Matricu- lates.	Notifica- tions.
Barnes Medical College	139	101
Marion Sims College of Medicine	273	7
Ensworth Medical College	23	2
American Medical College, Eclectic	47	0
Medical Department State University	48	0
Missouri Medical College	98	13
Central Medical College	19	1
St. Louis Medical College	30	7
Kansas City Medical College	45	13
Homeopathic Medical College	8	0
St. Louis College Physicians and Surgeons	86	13
Beaumont Hospital Medical College	38	5
Woman's Medical College and Hospital Asso- ciation	1	0
Total	855	162

These figures do not show the entire attendance, but they give an approximate idea of the relative attendance at the various schools. The most disturbing factor in the matter is the necessity of the Board to reject certain matriculates found in some schools that had been already rejected at other schools for lack of qualification. The Board is worthy of all support in its effort to elevate the standard of students, and it is to be hoped that no combination of influence will prove effectual in opposing it in its good work. Such a step as this will go far to overcome the prejudice that has been fostered against St. Louis as a center of medical teaching.

Philadelphia Notes.

THE TWENTY-SIXTH ANNUAL MEETING of the Jefferson Medical College Alumni Association was held on the 18th inst., Dr. E. E. Montgomery, President, in the chair. He congratulated the members upon the fact that through their efforts "the college had been reorganized, the faculty salaried, the institution made partaker in the profits of its success and relieved from the stigma of being a coöperative institution for the benefit alone of its faculty." Since the last meeting of the Alumni Association the chair of ophthalmology had been established in just recognition of the long and arduous services of Professor Thomson in the clinical work. The chair of pathology has been established with a salary equal to that received by any other professor in the school. This chair has been filled by the trustees by the election of Dr. George Dock, now Professor of Practice of Medicine in the University of Michigan. "After careful consideration the board of trustees and the faculty have decided that it would be unwise to remove from the central portion of the city, and consequently the large six-story building to the south of the college has been procured for additional laboratory and clinical purposes. The determination to remain at the present location and the increased needs to meet the requirements of a four years' graded course, demand increased expenditure. Both college and hospital buildings should be remodeled in order to meet modern requirements." The establishment of the new chair of pathology affords the Alumni Association an opportunity to demonstrate its ability to be of service to the institution. "To properly equip this department will require the expenditure of at least \$10,000. The production of this sum of money the Alumni Association should accept as their work."

After the conclusion of the address, a motion was adopted pledging the association to raise \$10,000 for the pathologic laboratory, and a committee was appointed consisting of twenty-five members to solicit subscriptions. The first subscription was made from the treasury of the association, \$100 being appropriated on motion of the treasurer, Dr. E. L. Vansant. The executive committee are authorized to prepare a medal to be awarded as the alumni prize for scholarship at the final examination, on commencement day. The officers for the ensuing year are as follows:

President: Dr. A. K. Minich, of Philadelphia.
Vice-Presidents: Drs. A. P. Brubaker, J. M. Barton, Orville Horwitz, G. A. Horn, of Philadelphia; W. D. Foster, Pittsburgh; H. H. Drake, Norristown; H. G. McCormick, Williams-

port; W. H. Hartzell, Allentown; J. K. Lineaweaver, Columbia; W. B. Lowman, Johnstown; Thomas Addis Emmett, New York; P. S. Conner, Cincinnati, Ohio; R. Beverly Cole, San Francisco, Cal.; Daniel Shock, Camden, N. J.; Jos. H. Chandler, Centreville, Del.; Thos. B. Camden, Parkersburg, W. Va.; Jas. P. Duckett, Anderson C. H., N. C.; Frank S. Love, San Antonio, Texas; Geo. C. Barton, Minneapolis, Minn.; J. T. Eskridge, Denver, Colo.; George C. Savage, Nashville, Tenn.

Chairman of Executive Committee: Dr. Hobart A. Hare.

Corresponding Secretary: Dr. R. J. Dunglison.

Recording Secretary: Dr. Frank Woodbury.

Treasurer: Dr. E. L. Vansant.

PERSONAL.—The friends of Prof. Horatio C. Wood will regret to hear of a serious accident which occurred on the 16th inst., while he was riding his bicycle on his way to his afternoon lecture at the University of Pennsylvania. In turning out from the track to avoid a car, he fell heavily and was run over by a carriage. It was found that he had received a scalp wound and contusions of the body, but apparently no bones were broken. He soon regained consciousness and was taken home. It is hoped that he will be out again in a few days.

ETHER ADMINISTRATION.—In order to avoid irritation of the nasal passages during ether inhalation (for which Dr. Gerster, of New York, has suggested the preliminary application of cocaine to the mucous membrane of the nose), Dr. Thomas G. Morton has adopted the original method of occluding the nostrils with cotton, thus obliging patients to inhale through the mouth. This method has been in use for a couple of weeks at the Pennsylvania Hospital and has been found to work well. It has the advantage that if it becomes necessary to promptly resuscitate a patient, the plugs can be taken from the nose and free ingress of air permitted. The comparative absence of struggling on the part of the patient is quite noticeable, and the anesthesia is accomplished with a minimum of ether. The combined method of administration of oxygen with ether was abandoned after considerable experience as being slow in causing anesthesia and wasteful of the anesthetic.

ACADEMY OF SURGERY.—At the January meeting of the Academy of Surgery the oration was delivered by Dr. J. M. Barton, who devoted his time principally to the consideration of some medico-legal relations of fractures. The subject proved so interesting that it was decided to devote the February meeting to a general discussion of it.

IMPURE AND ADULTERATED FOODS.—The report of the Department of Agriculture for the last nine months, which has just been completed, contains the results of the work of Secretary Edge in the analysis of food-stuffs. Some of the discoveries of the department are of general interest. Salicylic acid is largely used in the preparation of jams, jellies, catsup, etc. This has been forbidden by the French government to be used for such purpose, as it is considered to be dangerous to the public health. Table mustard is practically never pure; of powdered mustard, two-thirds of the samples were found to be adulterated. Ground spices are seldom pure. Many fruit jams, strawberry, raspberry, etc., consist principally of starch paste, flavored with a small amount of fruit. French peas contain an injurious amount of metallic salts. An aggressive campaign has been conducted against imitation butter, but the recent conviction of vendors of oleomargarine proves that it is still in the market, and the same is to be said of cider vinegar. The work of the department in enforcing the pure food laws has been followed by excellent results and proves its establishment to be in the interest of true economy, since the annual loss in adulteration in the State of Pennsylvania is not less than \$20,000,000 at a conservative estimate.

Washington Notes.

WEEKLY REPORT OF THE HEALTH DEPARTMENT.—The report of the Health Officer for the week ended January 11 is as follows: Number of deaths (stillbirths not included): White, 86; colored, 60; total, 146. Death rate per 1,000 per annum; White, 23.8; colored, 34.7; total, 27.6. Death rate per annum corresponding week last year, 21.3. The death rate for the District of Columbia took a sudden upward turn last week. There were 27 fatal cases of pneumonia and 22 died of consumption. Four deaths from typhoid fever were reported, and

2 from gripe. Infant mortality ran up to 37 of those under five years old, of which 26 were under one year of age. The hospitals reported 23 deaths during the week, and the coroner certified to 14 deaths. The births reported were 112, and 39 certificates of marriage were received by the Health Department.

HEARING ON MEDICAL BILLS. There was a hearing before the Senate committee on the District of Columbia at 2 o'clock on Monday afternoon on medical bills relating to the District of Columbia. There are four of these bills before the committee, two by Mr. Harris, to regulate the practice of medicine and surgery, to license physicians and surgeons and to punish persons violating the provisions thereof in the District of Columbia, and to provide for the incorporation and regulation of medical colleges in the District, and a third bill by Mr. Morrill relating to the testimony of physicians in the courts here. The hearing had special reference to Mr. Harris's bill to regulate the practice of medicine and surgery in the District.

TO PROVIDE FOR INEBRIATES. Mr. Roach has introduced in the Senate a bill to provide for the care of inebriates in the District of Columbia. It is similar to a measure introduced in the House of Representatives by Mr. Meredith on December 9.

TO PREVENT CRUELTY TO ANIMALS. A bill for the prevention of cruelty to animals in the District of Columbia has been introduced in the Senate by Mr. McMillan. It provides that no person shall perform any experiments on a living animal calculated to give pain to such animal, except subject to certain restrictions. Experiments by licensed medical practitioners may be performed, but the animals experimented on are to be placed under the influence of anesthetics until before they are revived. A first offense in the violation of this law renders the offender liable to a fine of \$150, and a second offense to a fine of \$200 or six months' imprisonment.

WANT MONEY FOR HOSPITALS. The representatives from the Hospital Boards of the Eastern Dispensary, Home for Incurables and the Central Dispensary and Emergency Hospital were given a hearing by the Sub-committee on Appropriations on the 18th inst. The claims of each were listened to with great interest and it is hoped that the institutions will receive what they asked for. They are all doing good and necessary work, and without doubt head the list of properly conducted medical institutions.

THE POST-GRADUATE MEDICAL SCHOOL. The Board of Trustees of the Post-Graduate School of Medicine held a special meeting on the 13th inst., to receive an important recommendation from the curriculum committee.

WASHINGTON MICROSCOPICAL SOCIETY. At the meeting of the Microscopical Society held on the 14th inst., Dr. V. A. Moore read a very interesting paper entitled "Morphology of Bacteria," and accompanied the paper with lantern slides.

MEDICAL SOCIETY. At the meeting of the Medical Society held on the 15th inst., Dr. Wm B. French read a paper entitled "The Malarial Organism with report of Cases." Dr. Gray exhibited by lantern slide some photo micrographs. The paper was discussed by Drs. Walter Reed, Kinyoun and others. This paper is second to none read before the Society and showed the practical work done by Dr. French at the laboratory and clinic at the Central Dispensary and Emergency Hospital. One of the cases was one of coma from acute malarial poisoning and it is believed to be the first case ever reported of the kind. Dr. J. E. Thompson presented the specimen of an extra uterine pregnancy at term, which he successfully removed from a woman about fifty years of age. The pregnancy was supposed to have taken place four years ago. The fetus and placenta were almost absorbed. Dr. Robt. Fletcher, U. S. A., formerly of the Columbia Medical School, has been elected an honorary member of the Society.

WASHINGTON OBSTETRICAL AND GYNECOLOGICAL SOCIETY. The 250th meeting of the Society was held on the 17th inst. Almost the entire evening was taken up with the discussion on Dr. Kelley's paper on "Fibroid Uterus and Pregnancy." Dr. Stanley, of the Garfield Hospital was an invited guest at the meeting. Dr. Van Rensselaer presented a disorganized appen-

dix with concretions which he had successfully removed. Dr. T. C. Smith presented a proscribed hollow mass which he removed from the uterus of a woman. It was referred to the microscopic committee for report. Dr. J. T. Johnson presented a uterus which he had removed per vaginam for cancer far advanced. Dr. Fry presented a uterus which had been performed as a result of abortion. The operation was followed by total suppression of urine for five days. He had reopened the abdomen to be sure the ureters were not included in the ligature. Sepsis was probably the cause of the suppression.

THE PUBLIC SERVICE.

Army Changes. Official list of changes in the stations and duties of officers serving in the Medical Department, U. S. Army, from January 11, 1896, to January 18, 1896.

Major Curtis E. Munn, Surgeon (Benicia Bks., Cal.), is granted leave of absence for two months, to take effect on or about Jan. 21, 1896, with permission to go beyond sea.

First Lieut. James M. Kennedy, Asst. Surgeon, is relieved from duty at Camp Merritt, Mont., to take effect upon the expiration of his present leave of absence, and ordered to Ft. Missoula, Mont., for duty.

Capt. James D. Glennan, Asst. Surgeon, leave of absence granted is extended one month.

Marine-Hospital Changes. Official list of changes of station, and duties of Medical Officers of the U. S. Marine-Hospital Service, for the fifteen days ended January 15, 1896.

Surgeon G. W. Stoner, granted leave of absence for thirty days with pay, and not to exceed sixty days without pay, Jan. 15, 1896.

P. A. Surgeon W. J. Pettus, granted leave of absence for thirty days, Jan. 2, 1896.

P. A. Surgeon G. M. Magruder, leave of absence extended nine days, Jan. 2, 1896.

P. A. Surgeon H. T. Goodwin, granted leave of absence for sixty days, Jan. 4, 1896.

P. A. Surgeon A. C. Smith, directed to investigate relative to smallpox in Mississippi and Crittenden Counties in Arkansas, Jan. 14, 1896.

Asst. Surgeon C. H. Gardner, ordered to examination for promotion, Jan. 4, 1896. Granted leave of absence for thirty days, Jan. 15, 1896.

Asst. Surgeon J. A. Nydegger, ordered to examination for promotion, Jan. 8, 1896.

Asst. Surgeon H. W. Wickes, to proceed from New Orleans, La., to Memphis, Tenn., for temporary duty, Jan. 14, 1896.

RESIGNATION.

P. A. Surgeon H. T. Goodwin, resignation accepted, to take effect March 5, 1896.

Change of Address.

Akins, W. T., from 3433 Wabash Avenue to 180 Wilmot Avenue, Chicago, Ill.

Kerrigan, J. K., from 687 West Twenty-first Street to 1367 West North Avenue, Chicago, Ill.

Liliencrantz, A., from 819 Market Street, to 803 Sutter Street (corner Jones Street), San Francisco, Cal.

Von Rehm, E., from Chicago, Ill., to 59 West One Hundredth and Fifth Street, New York, N. Y.

ORIGINAL ARTICLES.

A CASE OF GASTROTOMY FOR THE REMOVAL OF HAIR-BALL—RECOVERY.

Read at the Quarterly Meeting of the Iowa and Illinois Central District
Medical Society, Jan. 9, 1896.

BY WM. L. ALLEN, M.D.

DAVENPORT, IOWA.

The case I report is not only unique as regards the character of the foreign body found, but instructive from a physiologic standpoint, showing as it does the remarkable ability of the stomach to digest food in sufficient amount to maintain a fair degree of health, even under the most trying conditions.

Case.—Maggie Heinz, aged 16, was brought to me in November last by Dr. De Armand. She stated that she had felt a tumor in the region of the stomach for the past six months; felt more or less pain after eating, vomited frequently, lost weight during the last twelve months and had frequent attacks of diarrhea followed by constipation.

Further questioning elicited very little history that would throw light upon the case. Examination revealed a tumor in the epigastric region, oval in form and movable several inches to the right or left; it was as hard as bone at the right extremity, apparently, but painless on moderate pressure.

Vaginal examination revealed normal condition of pelvic organs; her age, condition and the trivial symptoms manifested, precluded the thought of a malignant tumor of such size and rapidity of growth. The extreme hardness at the right border precluded the diagnosis of a floating kidney or spleen, consequently I advised that an exploratory laparotomy be made to determine the character of the tumor and the removal of same if found feasible. She consented to this and was admitted to St. Luke's Hospital on November 23.

On November 25, assisted by Drs. Crawford, Hageboeck and De Armand, I made an incision in the median line between the ensiform cartilage and the umbilicus, and after opening the abdominal cavity found the stomach presenting directly beneath the incision, the entire viscus being compromised by the tumor. On grasping the stomach it was at once seen that it contained a foreign body which completely filled the cavity, and which appeared to be nine or ten inches in length and very hard at the pyloric end. The abdominal incision was then extended below the umbilicus in order to give ample room, and the stomach with the contents drawn through the incision.

An opening in the stomach was then made parallel to the greater curvature and passing nearly to the cardiac extremity. The muscular wall was found to be about three times the normal thickness and the mucous layer was likewise thickened greatly. On opening the latter the tumor was found to be a mass of hair completely filling and distending the stomach, and it was necessary to carry the incision still farther toward each extremity, about five inches in all, and the mass was with difficulty brought through the gastric incision. A very little mucus escaped through the wound. The mucous membrane was united with a continuous silk suture and the serous coat with sixteen Lembert sutures, also of silk.

The patient vomited once while the mucous layer was being sutured. The stomach was found free and very clean. After removing the hair-ball there was no escape of any contents into the abdominal cavity. The abdominal wound was united with silk and the operation completed in one and one-half hours.

There was no shock following the operation: on the contrary the patient recovered from the effects of the ether almost the moment she was in bed. She vomited and was given a hypodermic injection of one-half grain of codein at noon, and again at night. Temperature two hours previous to operation was 99 4-5; at 6 P.M. it was 101; at 9 P.M. it was 100 1-5; pulse 116.

November 26 she slept well. Temperature at 6 A.M. was 98. Later it rose to 99 4-5 and then dropped in the evening to 98 3-5; pulse 103. At 6 P.M. she was given six oz. pep. milk per rectum: nothing by the mouth.

November 27, temperature at 6 A.M. was 98; pulse 98. At 6 P.M. temperature 100; pulse 79. She was given rectal injections of liquid peptonoids, which she retained, while the milk was expelled.

November 28 she slept well: retained liquid peptonoids per rectum given every eight hours. Pulse 70: temperature ranging from 98 to 99.

November 29 she slept well. Pulse 70: temperature 98. From this time on temperature remained at or below normal: pulse slow. Bowels moved every second day by enema.

December 1 she was given pep. milk by the mouth and complained of hunger. December 2, stitches were removed, union being perfect. December 9 she sat up. December 10 she was given solid food: no discomfort, but still hungry. December 20 she was discharged cured.

On questioning her after the operation as regards the hair-ball, she admitted that she had been in the habit of eating her hair ever since she was three years old, and up to two years ago. Had either bitten off, pinched or pulled out long ones, which she

HAIR-BALL REMOVED FROM STOMACH.

rolled around her finger into a ball or loop and then swallowed; for the last five or six years she remembers to have felt the tumor which seemed to remain about same size as when it was first noticed. The appearance of the foreign body is shown by the photograph herewith.

Its dimensions are as follow: Diameter, cardiac to pyloric extremity, 9½ inches; entire length including duodenal part, 17 inches; circumference at pyloric extremity, 8½ inches; circumference at greater curvature, 8½ inches; circumference at cardiac extremity, 5½ inches.

The first authentic case of gastrotomy was done successfully 1602, by Florian Matthis of Prague removing a knife from the stomach of a juggler and since that time, so far as I can find from the records, there have been thirty-eight cases, with thirty recovered, six deaths, and two uncertain. There have undoubtedly been other cases and very likely more unfavorable ones are missing. There are also several

cases recently of gastrotomy as a means of entering the esophagus, with two very interesting cases reported by Richardson and Bull.

HISTORICAL.

1. 1602, Mathis, Prague, knife, recovery.
2. 1635, Schwabe, Königsberg, knife, recovery.
3. 1692, Wesener, Halle, knife, recovery.
4. 1720, Hubner, Rustenburg, knife, recovery.
5. 1786, Frizac, Toulouse, knife, recovery.
6. 1819, Cayroche, knife, recovery.
7. 1822, Reynaud, Grenoble, knife, recovery.
8. 1823, Bertherand, spoon, recovery.
9. 1826, Fidei, Riva, fork, recovery.
10. 1848, Tilanus, Leiden, fork, death.
11. 1855, Bell, Davenport, bar of lead, recovery.
12. 1856, Gluck, laryngeal probang, death.
13. 1856, unknown, fork, recovery.
14. 1857, Bouchet, Lyons, fork, result unknown.
15. 1858, Hohlbeck, Wodkinsk, fork, death.
16. 1875, Labbe, fork, recovery.
17. 1880, Fleury, S. America, fork, recovery.
18. 1880, Bille, sponge and wire, death.
19. 1880, Felizet, spoon, recovery.
20. 1882, Hashimoto, Japan, tooth brush, recovery.
21. 1882, Schönborn, Königsberg, hair ball, recovery.
22. 1883, Kocher, Berne, probang, recovery.
23. 1883, Giessenbauer, Prague, sword blade, death.
24. 1883, Thornton, London, hair ball, recovery.
25. 1883, Gerard, Bourguell, a piece of wood, recovery.
26. 1885, Billroth, Vienna, set of teeth, recovery.
27. 1885, Credi, Dresden, set of teeth, recovery.
28. 1886, Bernays, St. Louis, knife, recovery.
29. 1886, Polakoff, Paris, fork, recovery.
30. 1886, Richardson, Boston, set of teeth in esophagus, recovery.

31. 1887, Bull, New York, stone in esophagus, recovery.
32. 1887, Loretta, Bologna, needle, recovery.
33. 1888, Berg, Stockholm, hair-ball, recovery.
34. 1889, Witte, Mt. Pleasant, fork, recovery.
35. 1889, Lowson, Bath, skewer, result unknown.
36. 1891, Richardson, Boston, safety-pin, recovery.
37. 1893, Cant, Lincoln, razor, death.
38. 1885, Allen, Davenport, hair-ball, recovery.

Total 38 cases; recoveries 30; deaths 6; unknown 2. The foreign bodies were found to be as follows: Forks 11 cases; knives 6 cases; hair-balls 4 cases; set of teeth 3 cases; spoons 2 cases; probangs 2 cases; needles or pins 2 cases; peach-stone 1 case; tooth-brush 1 case; piece sword blade 1 case; sponge and wire 1 case; skewer 1 case; piece of wood 1 case; bar of lead 1 case; razor 1 case.

Instances of hair-ball I find recorded as follow: In 1882, Schönborn, Königsberg, reported to congress of German surgeons at Berlin a case of gastrotomy for the removal of hair-ball from a young girl. She had been in the habit of biting off her hair. A tumor was found in the left side of the abdomen and was supposed to be either spleen or floating kidney.

In 1883 Knowsley Thornton, London, reported a similar case in a girl of 17 who was in the habit of swallowing the combings of her hair, from whom he removed a mass nine inches long.

In 1888 John Berg reported having removed a hair tumor from a patient in Stockholm. An exploratory operation was made and the mass found in the

stomach, which was opened and the hair removed in pieces. The patient denied having swallowed any hair since childhood. All of these cases recovered.

In 1891 Von Bollinger reports the case of a girl of 16 years who complained for three or four years of pain and vomiting, which so increased that she died. Before death, however, the tumor was discovered and a malignant growth of stomach was diagnosed. The autopsy revealed the stomach and duodenum very much enlarged, being about twenty inches in length, packed with hair, which extended down to the duodenum, resembling in shape the specimen now before you which also extended some three inches into the duodenum and is nine and one-half inches in its longest diameter and weighs one pound, seven and one-half ounces.

Poulet (*Foreign bodies in Surgery*, N.Y., 1880) gives the following cases not enumerated above: 1602, Crollins, knife; 1613, Guenther, penknife; 1635, Shoal, knife, 6½ inches long.

A surgeon-major at Nîmes, Fr., spoon. Duplay and Reclus (*Traité de chirurgie*, 7, vi., Paris, 1892) give the following additional cases: 1889, Terrier, fork; 1889, Périer, teaspoon; 1891, Heydenreich, spoon.

HIGHER EDUCATION FOR PHARMACISTS.

Read in the Section on Materia Medica and Pharmacy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY PROF. JOSEPH P. REMINGTON.

PHILADELPHIA, PA.

The AMERICAN MEDICAL ASSOCIATION has a deep interest in the education of the pharmacist; with improved methods and extended courses in the great medical schools, with the practices of medicine and pharmacy ever widening and developing, it must follow that better education for the pharmacist and more of it is imperatively demanded.

The first organized effort in America to instruct those who had entered the drug business resulted in the establishment of the Philadelphia College of Pharmacy in 1821; since then colleges have been established in New York, Baltimore, Boston, Brooklyn, Buffalo, San Francisco, Chicago, Cincinnati, Cleveland, Kansas City, Louisville, Toronto, Montreal, Washington, Pittsburg, St. Louis, Iowa City, St. Paul, Lawrence (Kan.), Ann Arbor (Mich.), Madison (Wis.), Atlanta, Albany, Newark, Columbus, Ada (Ohio), Lebanon (Ohio), Lafayette (Ind.), Richmond, Scio (Ohio), New Orleans, Nashville and Detroit. The first years of all of these institutions were struggles for existence; the difficulties which were encountered were serious, and if it had not been for a little band of faithful self-sacrificing friends of education, the efforts would have died from lack of appreciation. In looking back to these early days and in considering the educational work of the present, one remarkable fact stands out so prominently that it can not be overlooked—the elevation of pharmacy has been due almost entirely to the unaided efforts of pharmacists themselves, for the desire for self-improvement has been the motive which gave life in the early struggles and which to-day successfully supports the work.

Seventy-five years ago, all that was deemed necessary to qualify one to practice pharmacy was a cer-

tain number of years apprenticeship to the owner of a shop who had acquired his knowledge as he best could, by picking it up from an older person and from the few books which were then accessible. It is a surprising fact that not a single college has ever been endowed, and up to the present time practically nothing in the way of bequests from philanthropic friends of education has been received for these colleges. They are supported almost entirely by the fees of the students, and none of these students are compelled to enter the colleges to acquire an education, but attend solely because they realize the value of systematic technical knowledge in aiding them in the practice of their profession. Millions of dollars have been poured into the coffers of the great universities and medical schools to carry on their work, by public spirited citizens, and State aid is often secured for them, but while every one must recognize that general education is of the highest importance in developing our race, it is an astounding fact that pharmacy, which every one admits demands education of a special character and of a high order, has been left without any material assistance from public-spirited citizens outside of the profession itself; and this in the face of the evident proposition that this special education is primarily for the security of the public and the saving of human life.

The public mind is filled with horror and the editorial ink of the newspapers of the land is lavishly spent, when an unfortunate error in compounding a prescription sacrifices a life. But in the writer's knowledge never once has the editor of a public paper advocated the endowment of institutions of learning for the education of those members of the community into whose hands the safety of the lives of the public is committed. At the present time the buildings, property and equipment of the forty educational institutions for teaching pharmacy amount to several million dollars, and the credit for establishing and carrying forward this work must be given to whom it belongs, "the pharmacists themselves."

Of late years, pharmacy laws have been passed in nearly every State in the Union, but these laws differ in one essential particular from those which guard the practice of medicine. In the latter case the State board of medicine compels the candidate to show evidence that he has been systematically educated in a medical college, by requiring him to produce a diploma and then forcing him to pass an examination before a State board, but no pharmacy law has ever been passed in this country which compels a pharmacist to be a graduate of a college of pharmacy, before passing an examination. The pharmacist is permitted to practice and conduct a drug-store, if he passes successfully a State board examination. In some of the States these examinations are of a most trivial and imperfect character, and this condition of affairs has resulted in giving a legal standing to a large majority of those practicing pharmacy to-day, who have never been systematically educated at a college or university, and many of those who once secure their license to practice from the State board, stop there and never take the time, nor undergo the expense of obtaining a college diploma; in other words "they get as little as the law allows." But notwithstanding these adverse circumstances, the colleges of pharmacy are crowded and the facilities of many taxed to the utmost to give their students as thorough an education as is possible, thus proving

that the better class acquire knowledge solely for its recognized value. When the colleges in their early days were hampered by lack of means and by the struggle for existence, many of the apprentices were encouraged by their preceptors to stay away from the colleges, because of the argument that the preceptor could teach them more pharmacy behind the counter, than the college professor could from the lecture table; but this idea, although still prevalent in some localities, has largely given way since the colleges have proved their "reason for being" through the results which have been accomplished, and the student himself now feels that he can acquire a better knowledge of the underlying principles of his profession by availing himself of systematic instruction in the colleges, and moreover by supplementing this by drug-store experience. The immense additions to the materia medica and the enormous exploiting of new remedies have largely added to this condition, and we thus have an explanation of the general prosperity of these institutions. But there has also come with this, a deeper sense of responsibility on the part of the colleges and a sure determination to broaden and strengthen the foundation and to add to the superstructure, while at the same time demolishing that which has become superannuated or has outlived its usefulness.

In the demand for higher education it must ever be recognized that thoroughness in the essentials must never be sacrificed, and hence better methods for grounding the student in the underlying principles of every day practice have the first care. Renewed attention is continually directed toward preliminary education. The key to this subject is unquestionably found at the very beginning. The practice of pharmacy fortunately permits the acquiring of pharmaceutic knowledge during the novitiate of the student; the student of pharmacy has a great advantage in being able to labor at his profession, not only between the college courses, but while in actual attendance upon the lectures, and much instruction can be obtained from an intelligent and willing preceptor; and although the college may afford all of the facilities at its disposal, the daily and hourly contact with the preceptor exercises an influence for life upon the plastic mind of the tyro. The importance of only engaging such assistants, as have already shown that they possess a good English education, is of the utmost value. While it is true that we may have embryo Elihu Burritts still in existence, they must ever prove the exception and the preceptor who stamps his own individuality upon his assistants must see to it that the material which he is to mold and fashion should be suitably prepared to receive the instruction. If this be not done, the student entering college and mingling with his fellows is seriously handicapped, if not absolutely discouraged, by the difficulty of beginning a work late in life which should have been completed before entering a pharmacy.

The pharmacist must ever be the intelligent coadjutor of the physician, and yet it is recognized that preliminary education is the burning question in our medical schools, and is even of greater importance in this connection. In the higher education of the colleges of pharmacy laboratory instruction plays an important part, and it is in this direction that the future looks most promising. It is not intended by this to convey the impression that didactic instruc-

tion should be superseded, for there are a multitude of facts in pharmacy which can be impressed upon the minds of a hundred students at one time in the hearing of all, just as easily as upon one personally in the laboratory, but when didactic instruction is supplemented by the practical and personal performance of technical work in the laboratory, the significance of facts is vastly enhanced, and a familiarity in the actual handling of apparatus is secured.

The extension of college work to three full courses extending over three years has now become necessary to adequately embrace the consideration of all the greatly extended subjects of the lectures, and laboratory courses.

The physician who looks upon the druggist merely as a purveyor of drugs and considers that his duty is fulfilled when he can simply supply patients with the medicine that he has prescribed, will doubtless in the future awake to the fact that he can call upon an intelligent pharmacist to originate a special preparation in order to combat a certain disease; to analyze various products which have given unsatisfactory results, to accurately perform urine analysis, or to make a microscopic investigation which will lead to important results. Thousands of pharmacists to-day possess the necessary qualifications to thus aid the physician, and with the hearty assistance of the medical profession in the true scientific spirit of recognizing truth wherever it is found and in that broad liberality which casts aside prejudice and preconceived notions, the higher education of the pharmacist must be eagerly welcomed by the lovers of real progress in the medical profession.

INTRODUCTION OF LEPROSY INTO NOVA SCOTIA AND THE PROVINCE OF NEW BRUNSWICK. MICMACS IMMUNE.

BY ALBERT S. ASHMEAD, M.D.

LATE FOREIGN MEDICAL DIRECTOR TOKYO HOSPITAL, JAPAN.
NEW YORK.

Mr. Stansbury Hager, in an article entitled "Micmac Customs and Traditions," in the *American Anthropologist*, January, 1895, suggests the possibility of some connections between the Micmac tribes of Nova Scotia and the Mayas; these are the pre-Columbian game of Woltstömikwon, and the peculiar signification for the division of time of certain numbers in the same game, with both nations. There is also the signification of the arrow in this same game, among the Tiahuanacos of Bolivia and in the myth of the Navajo story of the Apaches. Similar mystic resemblances are found in the serpent dances and the Pleiades of these different nations, in Yucatan, Peru, Mexico, etc.

In a note to my article "Pre-Columbian Leprosy" (*JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, April, May, June, 1895), I suggested the possibility of an Indian migration from the Southwest, and intimated that if leprosy was pre-Columbian in Mexico and Peru, the leprosy of the Northeast might have its origin by immigrations from the Southwest of North America.

Speaking of this note, Mr. R. G. Haliburton, the well-known authority on the Micmacs, and founder of the Nova Scotia Institute of Science, says:

There is no connection between the Mayas and the Micmacs. What may have been regarded as some evidence was even more applicable to three-fourths, or rather nine-tenths of the North-

ern tribes. . . . I never heard that there was leprosy among the Micmacs. Still, that does not in the least prove it does not exist. But it does among the Acadians who live on or near the Bay de Chaleur at the mouth of the river St. Lawrence. You of course know the lazaretto at Tracadie, New Brunswick.

Strange to say, there are more lepers among the Acadians in Louisiana than any other race of their numbers. There are also a certain number of idiots, which may indicate a racial degeneracy. You have perhaps seen my paper on "Survivals of Dwarf Races in America." I suggest that idiocy among the Mexican dwarfs and those of the Pyrenees is the result of a race dying out, a race of hunters no longer able to get flesh food.¹

I also find among the Louisiana Acadians, that in Old French (perhaps it is so in modern French) the word cretin has no significance connected with goitre. It is a contemptuous word meaning merely a dwarf in mind and body—a stupid little man.

I may add that the Acadians are smaller than the people of Quebec, many of them not exceeding five feet in height. I have never heard that leprosy has been found in the Province of Quebec. But my ignorance on that point argues nothing, as I have never specially looked into the point, a *sine qua non* for an opinion worth anything.

Negative evidence in such matters is almost worthless. I do not think there is leprosy among the cretins of the Alps or Pyrenees.²

But cretinism and leprosy seem to belong to diseases caused by degeneracy.

He says in another letter:

I doubt the existence of leprosy among the Micmacs, and fancy they and the French Acadians have been mixed up together by some inquirer on whom you depend.

Dr. A. C. Smith, superintendent of the Leper Asylum, Tracadie, Province of New Brunswick, writes me:

Leprosy exists in Nova Scotia only in the descendants of highland Scotchmen who emigrated in the early part of this century. There is no leprosy in the Acadian families, and none in the Micmacs.

There is no cretinism, no goitre, etc., in the province, so far as I have been able to learn. None in the families of the Acadian lepers of New Brunswick. The lepers of New Brunswick are degenerated French.

I have addressed the following letter to Dr. D. McN. Parker, a leading physician, and one of fifty years' experience, and to the Rev. George Patterson, D.D., who has written largely on local history, and has given considerable attention to the study of local archæology, both of Nova Scotia:

NEW YORK, Aug. 24, 1895.

Dear Sir:—Dr. J. G. MacGregor, Secretary of the Nova Scotian Institute of Science, Halifax, refers me to you for information on the subject of the origin of leprosy in Nova Scotia. I am interested in the subject of pre-Columbian leprosy, and take the liberty to inclose in another envelope a reprint of an article of mine on that subject. The final note in that article refers to an opinion of Mr. Stansbury Hager, that the Micmacs came from the southwest of America, and therefore must have been in relation with the oldest leprous races on this continent. Mr. R. G. Haliburton entertains opposite views, and contends that the Micmacs neither came from the southwest nor were ever lepers. Leprosy came with the French Acadians. Dr. Smith, of Tracadie, contradicts Mr. Haliburton. According to this author, the Micmacs were not lepers, neither is there any leprosy in the Acadian families: that leprosy in Nova Scotia is found only among the descendants of Scotch highlanders. Haliburton has published a very entertaining paper on the survivals of dwarf races in the New World. He believes that cretinism and leprosy belong to diseases caused by degeneracy. "There is," he says, "a certain

amount of idiocy among the French Acadians of Louisiana: moreover the Acadians are smaller than the people of Quebec, many not exceeding five feet." Among Mexican dwarfs and those of the Pyrenees, according to the same authority, idiocy is evidently the symptom of the decay of a race.

Dr. Smith, the leprologist of Tracadie, says: "There is no cretinism and no goitre in the Province of New Brunswick. None in the families of Acadian lepers in New Brunswick. The lepers in New Brunswick are degenerated French."

I myself have ascertained that among the lepers of Colombia (25,000) goitre is exceedingly prevalent.

You will see, by the enumeration of these facts, the drift of my research. Did leprosy exist in Nova Scotia among the Micmacs and was the country affected before the arrival of either Acadians or Scotchmen? Is leprosy an indication of decadence, as the goitre or cretinism seem to indicate?

I shall be very much beholden to you, if you will dispose in my favor of such experience and knowledge as you have acquired in this matter. Yours truly,

ALBERT S. ASHMEAD.

Reply of Dr. Parker:

DARTMOUTH, N. S., Sept. 5, 1895.

DR. ALBERT S. ASHMEAD, Dear Sir:—I beg to acknowledge the receipt of yours of the 24th ult., and to say in reply, that I have never met in my practice, as a medical man during the past fifty years, a single case of leprosy; and, while Halifax has been the center of my work, I have traveled all over Nova Scotia to visit cases of sickness, in consultation with other medical men.

I have never heard of a case of leprosy in the Micmac tribe of Indians—the only tribe we have in our Province. I think the Scotch, a very large portion of our population, are free from it, except in one locality—Lake Ainsley on the Island of Cape Breton, where it is said to exist.

I have written to Dr. Gunn, a practitioner in that locality, to inform me as fully as possible concerning the matter; I have also communicated with Dr. McDonald, the leading practitioner in Antigonish County which is almost entirely settled by Scotchmen, from the Highlands of old Scotland, and with Dr. Perrin of Yarmouth, in which county there is a comparatively large number of French inhabitants.

I have also requested the authorities of the Provincial Secretary's office to furnish me with all reports, if any, that may be on file in that department, bearing on the subject. As soon as I get replies from my medical friends, and a report from the Provincial government, I will communicate the information to you. In the meantime I remain,

Yours truly,

D. MCN. PARKER.

Reply of Rev. Dr. Patterson:

NEW GLASGOW, N. S., Sept. 4, 1895.

Dear Sir:—I received your note of the 24th ult., and also your pamphlet on pre-Columbian leprosy, for which I am much obliged. I have been interested in what you have written, but was somewhat surprised by the assertion in the note at the close, that leprosy was endemic in Nova Scotia. It will be news to most, and even to many of our doctors, that it exists at all for it is only recently that it has been discovered, and then only in one remote and small settlement in the island of Cape Breton. There it was introduced by a man named Macarthy, an Irishman, and it has spread through his family connection. Occasionally a case appears in a neighboring settlement, but always of one who has been connected in some way with the family. I am not sure whether there are any cases where the disease has been contracted by mere contact, or whether there has been some relationship, but generally it is by the latter. It is almost entirely confined to that family or to those intermarried with them. But the people around have an idea of the nature of the disease, and now avoid contact with them. So connected is it with that family that the people call it "the Macarthy." I have not seen an official report of the case, but you may be assured that this is the only case where it has been known to exist in Nova Scotia, and it is only recently that it has been brought to light. I should have said that the Macarthys are a very poor family.

As to the question of its being among the Micmacs, I have to say that there is all the evidence that can be got to establish a negative to show that it never has existed among them. The early French explorers who came in contact with them, and have written of their condition and customs. Cartier, Champ-lain, Lescarhot, Denys, etc., make no mention of anything of the kind. From the time of the English coming into possession, the government had official dealings with them, relieving their wants so and in such a way that if there had been anything of the kind, it must have come under the notice of the officials. But all the researches of myself and others,

¹ I wrote Mr. Haliburton as follows: As far as I have studied the matter, dwarfs appear to me pathologic subjects. Dr. J. P. West, of Bel-laire, Ohio, in the October number of the University Medical Magazine, mentions eight rachitic dwarfs in the Ohio valley: one a mulatto, three children of wealthy Scotch people. Dr. Morrow tells me that in his visit to Switzerland, he met over a hundred dwarfs in the San Martino Valley, along the road to the St. Bernard Hospice. Goitre was so common that a woman without it was looked upon as a freak. Dr. Taylor, of Princeton, Ontario, writes me he has treated 217 cases of goitre; among them were three dwarfs. Two of the latter had non-goitrous mothers at birth. Goitre developed subsequently in the mother of one, and a sister of the other dwarf. He claims that the majority born of goitrous parents have not the same mental caliber as those whose mothers are free from goitre.

—A. S. ASHMEAD.

² Mr. Haliburton evidently does not know of Bretagne, France, and the Gogots of the Pyrenees.—A. S. ASHMEAD.

among our records have found nothing of the kind. I have had a good deal of intercourse with old settlers, whose recollections or traditions went back to the early English colonization, and though they had much to say about the Indians, they never speak of any such disease among them. I was on intimate terms with Dr. Rand, the missionary to the Micmacs, and often conversed with him on matters connected with them. Not only did he never mention such a thing as leprosy, as existing among them, but I find that in his translation of the New Testament into Micmac, he merely transfers the word where it occurs, showing that they knew nothing of its existence, or they would have originally had or would have framed a word to denote it. Besides they never were very numerous, probably never numbering more than five or six thousand. If this disease existed among them 300 years ago, they must have become extinct by this time or it would have become generally prevalent among them. You may therefore consider it as well established as any proposition of a negative character can be that there ever has been leprosy among the Micmacs.

From what I have said as to the only manifestation of it ever known in Nova Scotia, it will be seen also that both the Acadians and the Highland settlers are free of it. Perhaps however you may have heard of it in New Brunswick and confounded that Province with Nova Scotia.³

There is one district of that Province, in which it has existed for a good many years. That is in some poor French fishing settlements to the north of the Miramichi River.⁴

Tradition if not history traces it to a French vessel which had been trading to the Levant (her name is preserved as *L'Indienne*) and which was wrecked at the mouth of the Miramichi river in the year 1758. It is said that infected clothing was distributed among the fishermen, that she had Lascars or some Orientals among her crew, who were under the disease. The wreck took place late in the fall, and the crew associated with the fishermen all winter. There are no authentic accounts so far as I know of the progress of the disease for some time. But in 1844, the disease had made such progress that the New Brunswick government erected a lazaretto, and took measures to compel all infected parties to be placed in it, and prevented from having any contact with persons outside. This has been continued to the present time, the institution being now under the control and management of the Dominion government. By the last report there had been, during the past year, received six, and died two, leaving twenty-two under the care of the institution. This has been about the average number for a number of years, and it includes all the known cases of leprosy existing in the Province. Measures were taken a year or two ago to place in the same institution the diseased parties in Cape Breton. The medical superintendent went down there for that purpose, but found only one diseased party. But it is believed that others were concealed. The Lazaretto is situated at Tracadie, in Gloucester County, New Brunswick, and I should think that any further information you desire might be obtained by applying to Dr. Smith, the medical superintendent.

Sincerely yours, GEORGE PATTERSON.

Under date September 16, Dr. Parker writes me further as follows:

I enclose you the documents referred to in the letter addressed to you a few days since, obtained from the Provincial Secretary's office. Also a letter from Dr. Gunn, of Cape Breton, and another from Dr. Perrin, of Yarmouth, all relating to the subject of leprosy in Nova Scotia.

It is evident to me that the Micmac tribe of Indians have never been afflicted with this disease. They are diminishing in number, and degenerating in character, as well as physically, but the *rites of civilization* have effected these results. Pulmonary phthisis and rum are the principal causes, aided to some extent, doubtless, by syphilis. My belief is that leprosy had no existence in Nova Scotia prior to the advent of the French and Scotch.

Cretinism can hardly be said to exist in our Province, but goitre is not unfrequently met with.

I may add that having traveled a good deal in the Province of Quebec, and being quite familiar with the physical development of the Acadians resident in certain localities in Nova Scotia, I have never been struck with the disparity in size and height said by Haliburton to exist between the French here, and those resident in Quebec.

I think I stated in my brief note of the other day, that I had no practical experience with the subject in question, although

³ New Brunswick continued with Nova Scotia to form part of Acadia or New France till it fell into the hands of the British after the conquest of Quebec. In 1784, New Brunswick was separated from Nova Scotia, and formed into a distinct province.—A. S. A.

⁴ The first British settlers came to Miramichi from Scotland in 1761. The French had settled there in 1639.—A. S. A.

I have been practicing my profession in Halifax for fifty years.

I very much wish I could furnish you with more material connected with the matter as the result of personal observation or with more extended and reliable data, derived from the observations of others, but such as I have I herewith submit to you."

The following is what Dr. Gunn, of Strathtown, Cape Breton, writes to Dr. Parker on this same subject:

There have been several so called cases of leprosy at and near Lake Ainslie, among Scotch and Irish settlers. So far as I have heard there have been no cases among the native Indians or among the French Acadians. It has confined itself chiefly if not wholly, to Highland Scotch and Irish families. As far as my memory can decide there were cases of a disease that somewhat simulated leprosy, at Lake Ainslie and southwest Margerie near by: and there are a few families in these localities still afflicted by the malady.

For myself I never regarded the disease as leprosy for the following and perhaps other reasons: The disease does not evidently spread by contagion, or the whole community would be afflicted by it, as there has been no attempt made to isolate the sufferers, till quite recently, when one or two patients were removed to a lazaretto in New Brunswick. If it were leprosy, surely it would have overspread the whole country before now. Nor is the disease so fatal nor so loathsome as leprosy is represented to be. Many of its subjects have worked for years on their farms while suffering from the disease. It seems to be strictly an hereditary disease. Another circumstance seemed to me to strengthen the opinion that the disease was not leprosy. In a case treated by me, there seemed to be quite an improvement for some time, under the treatment usually prescribed for constitutional syphilis, namely, mercury and iodid of potassium. I do not intend to speak dogmatically on the subject. It would ill become a person of experience. I merely state the facts and my own observations. One thing you can depend on, the disease is not contagious. One of the men removed to the Lazaretto, lived for many years with a family, man, wife and children on the most intimate terms, ate and drank, and I think, slept with the children. Yet the disease never broke out in that family: you would expect otherwise, if it were leprosy.

The following is an abstract of a letter of Dr. A. M. Perrin, of Yarmouth, to Dr. Parker:

About leprosy in Nova Scotia: It is said that it exists in Cape Breton, among those who dwell up the river, and also at the eastern end of the county of Antigonish. But I do not think the report is authentic. As to the Indians of Nova Scotia, I think the disease has never been found among them. There is a legend among the French of New Brunswick as to the origin of leprosy among them, viz., a wreck was found on the coast near Tracadie, and the Shore-dwellers took the bedding and clothing home and used them, and a short time after the disease broke out. This story may not be true, but it is the one told. As to the French of Yarmouth and Digby Counties, I have talked with Dr. J. E. Farish, Dr. Harley, and Dr. Smith, all of whom have treated the French in every part of the countries named, and from my own knowledge, I am positive that the disease does not exist with us. The Indians of Yarmouth and Digby, suffer from all the different grades of syphilis. I do not know an Indian child or man that is not syphilitic. I was born in Pictou County, and I read with old Dr. Donnelly, of Albion Mines: he was an expert in diseases of the skin, and I am certain, if he had met it among the Scotch of Pictou, he would have mentioned it. The Scotch of Cape Breton are descendants of the Western Islanders and Barra men.⁵ I have looked up the different habitats of leprosy and the western part of Scotland is not mentioned.⁶

⁵ Dr. Prince A. Morrow writes me: "It is a well known fact that leprosy persisted in the Scottish Islands long after its disappearance from England and Scotland."—A. S. ASHMEAD.

⁶ The first leper house was in Scotland 1170; in Norway in 1266. Leprosy was widely prevalent in Denmark, and in England and Scotland in the sixteenth century, from which last we have a notice of numerous cases of leprosy in Kilmear (County of Fife) in the year 1693. In 1693, a complaint was lodged by the procurator-fiscal, against the intruding of the lepers of Kilmear upon the privileges only proper to the burgess and freemen of Prestwick, by their resorting to the shoar and taking of certain timber and other wreck, and casting greater quantities of peats and turf off the common and moss, etc., they ordained that none of the said lepers of Kilmear do so under the penalty of an hundredth pund, *toties quoties*, to be paid by *ilk* and (each one) of them in case of fullyle (failure)—Records of Prestwick. The disease appears to have continued in the northern Islands of Scotland, long after it had disappeared from the mainland of Scotland and, indeed, all other parts of Great Britain. In Shetland it has been known for centuries. I have already made a quotation from Brand to show that it was at Lerwick as late as the latter part of the seventeenth century. In some districts of

I think Dr. Smith is wrong in the idea that Scotch brought it to Nova Scotia, and I am certain that Dr. Ashmead will not succeed in finding it among the Micmac Indians. I sent an article to the *Venerical and Skin Journal* of New York, on the treatment of leprosy in the Sandwich Islands by native doctors and on the use of *Ara Ara* by the natives themselves: by its use they can hide it for years. I will hunt it up and send it to you. My knowledge was derived from a man who had spent his life among the natives on the Samoan and Sandwich group.

Here are some official reports which Dr. Parker has been kind enough to communicate to me.

PORT HOOD, C. B., May 4, 1888. *Hon. W. S. Fielding, Provincial Secretary, Halifax, N. S.*:—In reply to your communication of the 17th ult. requesting me to forward you a supplementary report on the existence of leprosy in this county, and asking me to suggest steps, with a view to the prevention of the spreading of the disease, and the preservation of the public health, I beg to submit the following:

This appears to me a most important question and, under all the circumstances, a both delicate and difficult undertaking. Within this range are two classes, viz., 1. Those already suffering from the disease, as exhibiting symptoms of leprosy or a skin disease allied to it. 2. The other class, where the disease is latent, not exhibiting any of the symptoms indicating the existence of any skin disease allied to leprosy.

This disease should be treated by thorough segregation in every case and interdiction of marriage.

The only hope of exterminating leprosy lies in the adoption of hygienic measures tending to improve the general condition, physical and moral, of the leprosy poor.

Medicinal treatment is of no avail unless combined with the regular use of suitable diet and clothing, protection against the vicissitudes of American climate, personal cleanliness, and ample exercise in the open air.

Many in the immediate neighborhood of these leprosy cases believe that the disease is contagious. I see no reason why, under some circumstances, the disease might be contagious, on the same principle as inoculation with smallpox or syphilis.

Shetland it continued still later. Apparently most of those there affected either belonged to or were sent to the Island of Papa. I have in my possession a manuscript extract from the session books of Walls, showing the expenses incurred in keeping the lepers at Papa, 1736 to 1740. Four of them appear to have died during these years, and two of these entries are for "tobacco" (probably used as a disinfectant as was usual at Scotch funerals). In 1742 there is a long entry in the Session Records of Walls, earnestly enjoining a day of public thanksgiving for the supposed total deliverance of the country from the effects of leprosy. The disease was not, however, eradicated entirely. Mr. Jack, the resident clergyman who wrote the account of the Parish of Northmaven, for the Statistical Account of Scotland, published in 1798, seems to have seen "several miserable cases" of the disease, and adds, that in many instances, there is reason to suspect a hereditary taint. Dr. Thompson urged his pupil Dr. Edmundston, of Lerwick, to trace out the history of the disease in the North, and that gentleman has made the following observation upon it in his work on the Zetland Isles (Ancient and Present State of the Zetland Isles. Vol. II, p. 102): "Elephantiasis known by the name of leprosy, was very frequent in Zetland about sixty years ago, but its occurrence since that time has only been occasional, and at present scarcely an instance of it is to be met with." He saw a true case of elephantiasis a few years ago, "face bloated, skin scaly and rough, and voice slightly hoarse." The termination was not fatal, and it did not communicate itself to others. The last instance he saw was a boy. There was no reason for the outbreak, and friends said it came on spontaneously and proceeded gradually. He says that "leprosy has long continued to linger in the neighborhood of the Farøe Islands, and in Iceland, that it was very common in the Middle Ages." He quotes Debes (*Færoæ et Færon Reserata*, etc., pp. 101 and 311, and *Acta Medica*, etc. Hafniensia, Tom. I, p. 98, London, 1659) that true tubercular leprosy continued to prevail in the Farøe Islands (the nearest land north of Shetland), in the middle of the seventeenth century. Still later, viz., in 1768 Petersen found 280 lepers in the hospitals in Iceland. It still prevails in Norway and Sweden. "As far as I am acquainted with the subject," he says, "it appears to me that under the name of radesyge (Scandinavian) two, if not more distinct species of disease were by Holst and the other authors who first wrote upon it, confounded and described together. One of these, the radesyge, properly so-called, is probably nearly allied to, if not identical with the sibbens of Scotland. Another of the supposed varieties of the disease, the spedalskhd, or Spetilska seems, on the other hand, to be a different nosologic species, hereditary, non-contagious, chronic, incurable, and identical in many of, if not in all its characters, with true tubercular leprosy." (J. Y. Simpson, Antiquarian notes of leprosy and leper houses in Scotland and England, Edinburgh Med. and Surg. Jour., 1841, 1842.) Papa lepers and Farøe Island lepers had all the characteristics of tubercular leprosy.

"One of the last, if not the very last Scotch leper," says Simpson, "was in the hospital wards of the Edinburgh Infirmary in 1798. John Bernis was his name, his age 28." Bergen, Norway, is the part of the continent of Europe nearest Shetland. In the thirteenth century, leprosy had reached "far north" in Scotland. There was a leper hospital in Elgin (a parish 118 miles north of Edinburgh) in 1226, that is before that of Bergen, Norway, 1266. The Hebrides islands, off the west coast of Scotland, belonged formerly to the kings of Norway, and in 1264 were annexed to the crown of Scotland. Everybody knows that the ancient Kings of Scotland themselves had been lepers for centuries.

Barra men, from the Hebrides went to Nova Scotia. The Farøe islands, 170 miles northwest of the Shetland islands, were originally peopled by Norwegians. In the Shetland islands leprosy had almost disappeared in 1742. In the Farøe islands, leprosy disappeared in the middle of the eighteenth century.

Ulcers and all open wounds, with their accompanied secretions, should be regarded as possible sources of infection by attendants and members of the patient's household.

All the neighbors are alarmed at the proximity of the disease to their house. I beg to state one case in illustration, that of John Gillis, residing in Egypt: the family consisting of himself, his wife and several children, are in very poor circumstances: no outsider will approach his house, mingle with them or assist them in putting the crop, down, etc., while he resides in the house, but if removed the neighbors I believe would attend to the wants of the family.

In class 2, I beg to recommend care and attention to cleanliness, avoid partaking of food likely to generate the disease. To watch families where the disease is hereditary, among whom may occur a constitution debilitated from some unknown cause. The disease usually shows itself from 15 to 25 years of age.

Your obedient servant, JOHN CAMERON, M.D.

NEWCASTLE, N. B., Dec. 17, 1895. *Hon. W. S. Fielding, Provincial Secretary, Halifax, N. S.*:—By direction of the Honorable the Minister of Agriculture I made a personal and professional examination, last summer, of alleged cases of leprosy on Cape Breton. Obtaining lists of supposed infected persons and families from clergymen, physicians, and other leading men, and following closely in the wake of the medical gentleman who, by direction of your Government, had, the year before, made an inspection of the district, I spared no pains to make my visit as fruitful of results as possible. For many days, from sunrise to dark, I was in motion climbing hills and visiting out-of-the-way places: and, while not disposed to make light of a serious matter, I have no hesitation in saying that many of the newspaper reports concerning leprosy in that section are exaggerated and sensational. Though a limited number of cases had existed on the island, I reported to the Minister but three living, all of whom have been, or shortly will be segregated. The Minister is thoroughly alive to the great necessity of stamping out this focus of leprosy, and is maturing his plans to that effect. Certain diseases resembling leprosy are also found there; the distinction, however, is to be made by an expert, not by a newspaper correspondent. Among these can be mentioned sibbens, one of the most horrible and contagious forms of skin disease, which has been the cause of many repulsive deaths there. As this malady can be diagnosed from some of the stages of leprosy only by an expert, it would seem to be wise for me to deal with it, and also to advise with local physicians and boards of health respecting its dangerous nature and treatment. Such a course would effectually silence those who for years have troubled the world with alarming reports of the prevalence of leprosy on the island.

Beyond the possibility of natives of Cape Breton meeting with difficulty, when abroad, in securing employment, because of supposed recent contact with persons suffering from leprosy, or kindred diseases—a matter referred to with some show of reason by a correspondent—it would be hard to adduce any motive of general reason apart from purely Provincial interests for dealing with diseases resembling leprosy from a Dominion standpoint. In view of the above considerations and within the limits referred to, I beg leave to suggest that I have conferred on me the powers usually given to boards of health, all my services to be rendered gratuitously, and no step involving any expenditure of money to be taken without first having obtained the assent thereto of the Honorable the Provincial Secretary.

I have the honor to be, Sir, Your most obedient servant.

ALFRED C. SMITH, M.D., C.M., etc.,

Inspecting Physician to the Hospital for Lepers, Tracadie, N. B.

PORT HOOD, C. B., March 19, 1888. At the request of the Provincial Secretary, on the 1st inst., to investigate the existence of leprosy or a disease akin thereto in this county, I beg to state that I visited and examined carefully several cases

The first observations belonging to this group of phenomenal occurrences comes from Scotland in the middle of the 17th century at the time of Cromwell's invasion of the southwestern districts of that country, a disease appeared under the name of sibbens (or sivvens), which was afterwards (1694) carried by the troops to the Highlands. (See Freer, Diss. de Syphilide nec nom de morbo Sivvens dicto, Edinburgh, 1707, and various other authors). Its greatest prevalence was about the middle of the 18th century in the southwestern counties of Dumfries, Kirkcubright, Wigton, Galloway, and Ayr; as late as 1825-1840, there were 60 cases of it, from Highland districts admitted into the Glasgow Infirmary, but since that time the name of the malady has disappeared from Scottish medical writings. Descriptions of the sibbens tend to show that we have to do here with severe forms of syphilis, with frambesia-like exanthems, and probably also with syphilis complicated with other diseases, especially of the skin (scalp). It appears that the malady was endemic mostly among the poor, filthy and neglected inhabitants of certain districts, and that it was spread not only by sexual intercourse, but also by contagion in other ways (wearing clothes in common, sleeping in the same bed, eating and drinking out of the same dish), as well as by heredity. (Hirsch.)

reported to me in the following districts, viz.: Lake Ainslie, Egypt, Lake of Law in North East Margaree and the Little Narrows. The parties affected with this disease, and their relations, appeared unwilling to give full particulars of this malady. I found their neighbors and others very willing to help me with the history of each case and apparently very anxious that the Government should take some steps to remedy the present evil.

First, I visited a family of the name of MacArty, at Lake Law, notorious for the existence of leprosy in the family. In the house at my visit were only the old man MacArty and a widow, his daughter-in-law. Old MacArty said that he was 97 years of age, a native of Ireland; considering his age in unusual good health. His wife, Betsy Hardy, came from Yorkshire, England; married her in Prince Edward Island. She is dead; was aged 64; was ill with leprosy for about five years, which caused her death. She had five sons and three daughters. Some of his family died with the same complaint, viz.: Richard died from leprosy, aged 50; John died from leprosy, aged 30; William died from leprosy, aged 24; Mary died from leprosy, aged 40. Married to John Doyle, family left for the States. It is supposed that John Doyle contracted this disease from his wife, as he also died from leprosy.

Living Henry MacArty, aged 49, in good health; Catherine, married to John Conner, aged 44; she is in good health; has six of a family; all reported in good health. John Conner died from leprosy, said to have contracted it from his wife, Susy, married to James Cameron, the latter said to have died from leprosy at Cheticamp about five years ago. The widow reported to be in good health. Two of this family are away in Boston.

Case 1.—Visited the house of James Harris. In the house I found his wife, a sick boy, and a young woman too much disfigured to be seen. Twice the mother tried to allow me to see her in her room, but she positively declined to see me. The mother allowed to be examined as to the present state of her daughter's health. She says that she is twenty-nine years of age and ill for about ten years. Supposed she took ill from a bad cold. She never attended a leprosy case or lived with any of those affected with it. She suffers from acute headaches; throat complaint; there is a fetid discharge from her nostrils; the nose swollen and ulcerated; her eyes inflamed and sunk in her head; some of her hair falling off; she is occasionally attacked with shiverings; her hands feel cold, not contracted, but of a dark color; the lower extremities somewhat anæsthetic, but toes not contracted; the skin over her face is rough and thick, with tubercles interspersed here and there. Diet: Lived a good deal on sour milk, bad quality of cheese, salt fish, such as cod and herrings, tea, bread and butter. I was told that Dr. Carmichael attended upon her, and that he would supply me with more information. I had called upon Dr. Carmichael and he said that he never attended upon her, but occasionally they sent to his office for medicine for her. Examined a near neighbor of the above case. Says he knows Mary Rachel Harris. Last time I saw her was, I think, in the fall; her eyes appeared sunk and inflamed; face swollen, tubercular and ulcerated. Nose destroyed by ulceration and exposing the bones of the nose. It is believed that she contracted her illness from Joseph Brown, an uncle who had died from leprosy. Brown was blind and deaf (sic) and she was constantly at his bedside reading to him. I am of opinion that the above case is an advanced stage of leprosy (tubercular form). The sick boy, William, 19 years of age, confined to his room since January; examined him and found no symptoms indicating leprosy, but an unhealthy looking subject, favoring the development of this dreaded disease. There are two other boys in the family, one in the house apparently well, and the other at sea. James Harris and wife are well, but his wife's brother, Joseph Brown, died from leprosy.

Case 2. John Gillis, residing in Egypt, aged 50; ill since about eighteen years of age; can not leave his house, but will move freely enough inside the house. Appearance: Face tubercular, irregular and shining, particularly over the cheek bones; the nose broad and flattened, caused by ulceration and the parts healed, afterward leaving cicatrices; the eyelashes are destroyed, with a cluster of tubercles over the upper eyelids and forehead. The ears peculiarly thickened and elongated; the voice very husky and hoarse. Throat examined, fauces of a pale appearance, uvula almost disappeared. The pharyngeal region appeared as if minute ulceration existed in the mucous membrane. Both hands are of a blue color, rough

and tubercular, all the nails disappearing and in a diseased state. Examination of the lower extremities, somewhat atrophied and wasted. Cicatrices of old sores from the knee to the foot; all the toes in a state of ulceration and will likely slough off; both legs are somewhat anæsthetic. Has cold shiverings and can not sleep well. Has no proper food. For several years could not work and no one comes to see him. He is very destitute. He has ten of a family, ages from 8 to 21. Some of them are not allowed to come near him, two of them are working at the C. B. Railway and send him any relief they can afford. The wife and children at home are apparently well. He had a brother, Donald Gillis, who died of leprosy at South-west Margaree; he was ill with it for about ten or fifteen years. His face and body were in a horrible state. He lost his sight by it. John Gillis' neighbors report to me that he wore some of his brother's clothes, that he was seen going to his place and was recognized while he was wearing them. John Gillis denies this; says he never took any of his clothes. Another brother, Angus Gillis, residing at Cheticamp, and married to one of the MacArty's, of Lake Law, is reported to me as suffering from leprosy. He went there from S. W. Margaree about a year ago.

Cases 3 and 4. Maggie McLean, aged 40, residing at East Lake Ainslie; illness began when about eighteen years of age. Her face apparently free of tubercles. Throat examined; the fauces of a peculiar pale color; nothing abnormal to be seen. Her hands and feet were found tubercular, with a few ulcers, swollen and contracted. She has difficulty in walking; attacked with cold shiverings sometimes; the legs and hands are benumbed as if want of feeling; her voice is clear; diet very poor: lives on salt fish, potatoes, tea and bread.

Christy McLean, aged 49, lives with her sister, Maggie McLean, the above case. Illness began when about twenty years of age. The same train of symptoms as in her sister's case.

Archy McLean, aged 40, a brother, died from leprosy nineteen years ago. He was ill for more than twenty years with it. There is a brother living, aged over fifty years, married and has six of a family. He is reported to be in good health.

Case 5. Duncan MacKinnon, residing near the outlet of Lake Ainslie, aged 42, appears to be upward of fifty years of age. He is a shoemaker by trade; unmarried. Examination: His face is much swollen and tubercular; nose enlarged and inflamed; there is a discharge of blood and matter from it; eyelashes destroyed; eyes sunk but not red; sight is good; hair falling off; ears tubercular and elongated like Gillis'. Examination of throat: Has peculiar red streaks running from above downward toward the uvula. The mucous membrane in the pharynx slightly ulcerated; spitting thick matter occasionally. Sometimes he is attacked with severe shiverings. He is very hoarse. His hands and feet are tubercular; both have less feeling in them than in health.

Case 6. Flora MacKinnon, wife of Malcolm Matheson, aged 33, residing at the Little Narrows. Her illness began about eight years ago; is of a much milder character than any of the rest. There are a few tubercles on her face and the marks of cicatrices are seen on her arm where sores existed at one time. She is able to attend to her household duties; is very active and useful. Attends to her health by medicines she receives from her doctor, which she says is of benefit to her. I could detect no constitutional disturbance. Has no attack of shiverings. She has six of a family, all are apparently in good health. The youngest is only a few months old and fed by the nursing bottle.

I had visited and examined several other families reported to me at Lake Ainslie, but were to all appearances free of any symptoms indicative of leprosy or any other disease akin to it. I shall be glad to give further information on some points which I may have omitted. I have the honor to remain,

Your obedient servant, JOHN CAMERON, M.D.

In answer to my inquiries as to the date of the outbreak of leprosy in the McArthy family, also as to where McArthy was exposed to the disease before he inoculated the country with it, and as to that other question whether he brought it from New Brunswick, Dr. R. G. Gunn, of Strathtown, Nova Scotia, writes to me:

I regret that at present I am unable to give you the desired information, but I shall endeavor to state a few facts bearing on the disease in question which may be of some interest to you, and shall try to get the dates asked for, or an approximation thereto, and write you again.

Whether McArthy's was the first case of the disease in this place, I am unable to say, but I am inclined to think there were other cases as early or earlier. That he had been in New Brunswick I doubt, but I will make inquiries. I am satisfied, how-

* Dr. Smith, of Truro, writes me: Betsy MacArty, the first of the family to show symptoms of the disease, came from Prince Edward Island; she was born in Lincolnshire, England, and married in 1826. In 1852 she became afflicted with leprosy. Several of her sons died of the same disease.—*Ashmun.*

ever, that the McKinnons at Lake Ainslie had no direct communication with McArthy. With them it seemed to be a family disease, rather than the result of contagion. There are two cases at Lake Ainslie now in the McLean family, which are said to be leprosy, and for whom county funds are annually paid on the assumption that they are real cases of leprosy. These are not, so far as I know, connected with the McKinnons or McArthys. Near by is a young man connected with the McKinnons, who is supposed to be in the incipient stage of the disease. The most marked symptom in his case is loss of the eyelashes and eyebrows. Would these be suspicious symptoms?

A marked symptom in the only case that came under my supervision was huskiness and weakness of the voice, showing that the larynx was involved, and arousing suspicion of syphilis. This symptom is, I am told, always present in the cases of so-called leprosy in this place. There was also much swelling of the face with many nodular tumors, and a dusky purplish hue of the skin. There was also swelling of the hands and feet with nodes or small tumors around the elbow joints. The swelling of the face latterly became extreme, the eyes being almost hid. The hands also were much swollen and somewhat distorted, rendering any kind of manual labor extremely difficult. So far as I remember there were no ulcers. The skin was unbroken. The skin, however, looked quite scaly and unhealthy. Such is a brief and very unsatisfactory sketch from memory of a case seen by me several years ago.

I have received the following letter (dated Oct. 23, 1895) from Dr. John Cameron, Port Hastings, C. B.

Your queries are the following:

1. If leprosy existed in Nova Scotia among the Micmacs before the arrival of Acadians or Scotch? 2. Is it a disease affecting only degenerates in Nova Scotia, families with goitre, cretins or idiots? 3. What is the date of the first case in the McArthy family of Cape Breton? 4. Did McArthy bring lep-

CAPE BRETON LEPER.

rosy from New Brunswick, or another leper country? 5. Do you think the disease originated in Nova Scotia from infected fish diet, water or soil?

Answers: 1. I think not. 2. It appears so to me. 3. Date not exactly known, but supposed to be about 1845. 4. From New Brunswick. 5. No, but such diet would very probably bring the disease latent in a constitution to full development of the disease.

At Lake Ainslie, a Scotch settlement, there is a strong opinion still prevalent among them that the disease originated first from one or more parties who served as soldiers in the plains of Egypt, and had carried the disease into this country, about the year 1825. A number died from this disease at Lake Ainslie, not mentioned in my report. Since my report I had a case of elephantoid enlargement of scrotum in that locality, a disease evidently hereditary and probably taken by the same party from the east, where it abounds.

I addressed the following letter to Dr. Gunn, of Strathtown, N. S.:

May I trouble you again to obtain for me a photograph of a Nova Scotian leper, and one of a Nova Scotian sibbens. Now, as to the question you ask me, Would the loss of eyelashes and eyebrows be a suspicious symptom?

In Japan, however, many symptoms of approaching leprosy may occur, it is only when the lashes and brows fall, that the common people recognize the disease.

Dr. Smith sends me two photographs, one that of a Cape Breton leper, the other of a Tracadie leper. He remarks: The Cape Breton leper is one of two sisters afflicted in exactly the same manner. The feet are affected in a similar manner in both cases.

The disease, which has some resemblance to rheumatoid arthritis, is without doubt lepra mutilans. I have to make my diagnosis of the Nova Scotian cases, between that hydra-headed monster syphilis and sibbens and leprosy. That leprosy exists in Nova Scotia there is no manner of doubt. In addition to the general symptoms, the march of the disease, etc., the microscope shows the sections filled with leprosy bacilli, and there is the histologic structure of the disease.

"I did not use the word 'degenerate' in the meaning you used it. Our French are not undergoing evolution to a better life. Theirs is a clear case of reversion toward their tertiary ancestors."

Dr. Parker, in answer to my request for photographs, says: "I am about 250 miles from the place, and have no means of procuring photographic representations of their features, or anything that would illustrate the physical condition of other portions of their bodies. I have understood that they and their friends dislike their being brought in contact with persons outside of their immediate families, and if this is the case, the matter would hardly be accomplished by open measures."

TRACADIE LEPER.

Dr. Gunn appreciates the difficulty, and says at the close of his letter to me, "I will, however, make inquiries and communicate with Dr. Ashmead on the subject if the difficulties in question can be overcome."

Dr. Gunn "fears that it will not be easy to get the desired photographs. All the subjects of the disease in question that I know of live in remote country districts far removed from a photo-saloon. Beside, they would probably raise serious objections to the proposal of having their pictures taken. Possibly these, by no means unnatural objections, can be removed. I will make inquiries as soon as convenient and will let you know the result of my inquiries."

Regarding a relationship between the Mayas of Mexico, and the Micmacs of Nova Scotia which is claimed by Mr. Stansbury Hager, and a possible connection between the Mayas and ancient India, which is believed in by Le Plongeon I give here a letter I wrote to Edward H. Thompson, F.R.G.S., Merida, Yucatan. The letter which follows my own is the answer of Mr. Thompson.

9 Of this case Dr. Smith writes: "That poor fellow—one of several who lived close to leprosy families—is now dead and I regret not having any photograph of him to send you. But if you will examine plate 8 of Leloir's 'La Lèpre' you will find so close a resemblance to his face that no photograph could come much nearer."

MERIDA, YUCATAN.

MR. EDWARD H. THOMPSON, F.R.G.S. *Dear Sir:* Mr. Mercer (Henry C. Mercer, Curator Section of American and Prehistoric Archaeology, University of Pennsylvania) tells me to write to you for information about the question of pre-Columbian leprosy in Yucatan. Le Plongeon claims to have found representation of negroes, Mongolians, Burmese, which show at any rate, a relation with India, that is with a leprosy country. He says that there was among the Mayas of Yucatan, a name *naycan* meaning to rot, which he supposes to stand for leprosy; in that case it would have been before the Spaniards. Dr. Muniz, of Peru, believes that leprosy existed among the Incas, before the Spaniards. His proofs are the loss of nose and upper lip, visible on huacos pottery. But as these same samples of huacos pottery, show no deformation of fingers and toes, which is the most frequent and absolutely necessary symptom of mutilating leprosy, it is reasonable to suppose that such deformations are intended to represent not leprosy, but lupus or syphilis.

Will you please tell me whether in your extensive explorations, you ever found any representations or ordinary monuments, or any pottery, or any pathologic evidence in bones (pre-Columbian), which make you believe that leprosy in this country was pre-Columbian.

Yours truly,

ALBERT S. ASHMEAD.

QUINTA ACADIA, MERIDA, YUCATAN, Oct. 10, 1895.

DR. ALBERT S. ASHMEAD, *My Dear Sir:* . . . Don't build too much on Le Plongeon's theories and claims. Not a single point of contact between the old and new worlds before the Columbian era can be proved by monuments or facts so far found in Yucatan, or adjoining provinces. The Maya word you quote may have in the olden times referred to leprosy. *Nay-can-Kanay* is used to-day as the term for a leper. Yet my opinion is that in the old times it was used more for consumption, phthisis. *Nagal* is used when one is fainting from extreme debility. I have found many skeletons, but have never observed the evidences of leprosy.

Sincerely yours,

EDWARD H. THOMPSON, F.R.G.S.

It seems to me then that we must conclude: 1. That there is no leprosy among the Micmacs, and never was. 2. That in Nova Scotia leprosy exists in one Irish family, in the Island of Cape Breton, and only among the descendants of Scotch Highlanders in other parts of the Province. The original MacArthy leper came from New Brunswick, date of his leprosy supposed to be 1845. It may have come from Egypt; it was, according to tradition, brought by soldiers in 1825. 3. That in the Province of New Brunswick leprosy was introduced by a French vessel from the Levant, in the year 1758, and the disease is there still among the "degenerated" French."

¹⁰ The first French case of leprosy in Vermillion Parish, Louisiana (Mme. Ourlance) came from the south of France, 1866. Several of the family were afterward afflicted; also a nurse who waited on her, and a young man who had slept on the same bed. (Leprosy in Louisiana, from Annual Report of the Board of Health for the year 1880.) From general results of the investigation of leprosy in the Bayou La Fourche, Louisiana, I quote the following: "The entire region of country traversed by the Bayou La Fourche is low, level, alluvial land, which slopes back from the river to the cypress swamps and marshes. This region is adapted by soil and climate to the cultivation of rice, sugar cane and orange. Below Hurang's canal along both banks of the bayou, toward the Gulf of Mexico, the narrow strips of land are thickly populated by small farmers, and in many instances the habitations arranged behind the levees are surrounded by rice fields. It is evident, therefore, that the inhabitants of the lower La Fourche are subject to the constant action of a low, moist, malarial atmosphere. Another point of interest in this inquiry is that the diet of these people consists largely of rice, fish and wild birds and animals, as the different variety of duck, crane, snipe, woodcock, raccoon, opossum, squirrels and rabbits. It is said that a fish-eating people are ill-nourished, and in eastern countries are particularly liable to become leprosy. If this be so, it must be associated with such poverty as prevents the inhabitants from obtaining a proper variety of fresh food and vegetables. Certain districts of the Mediterranean coast of Spain are cited in illustration of these facts, where there is a fish-eating and a poverty-stricken population; and if we turn to another fish-eating community—that of part of the west coast of Norway—we find the disease, although some of the people are characterized by robustness of health and great physical strength.

It is possible that the prolongation of the leprosy in this and similar regions, while it appears to have gradually become extinct in the more elevated and healthier portions of Louisiana, may in a measure be due to the effects of climate, soil and food; but from the result of our investigation we are convinced that in its first origin the disease must be traced beyond the confines of this State, to the southern states of Europe, and to the coast of Africa. In other words, the disease on the lower La Fourche has been propagated by hereditary influences, and by personal contact rather than engendered by climate, soil or food. The

Some say that there is an etiologic relation between the fish diet and leprosy.¹¹ Witness Norway, Japan, China, Coasts of Spain, etc. Leprosy in Nova Scotia and New Brunswick might be also quoted to corroborate such views. There is, as is well known, an immense fish trade going on in those provinces. Nothing is more conceivable than that the bacillus, through an intermediary, finds in the fish a suitable soil for spontaneous culture or preparation for a further development in the human body. Climatic factors, producing certain nervous conditions in the human organism, like, for instance, syringomyelia, mal de San Antonio, scleroderma, Raynaud's disease, etc., a prebacillary stage, may allow the bacillus to be inoculated, and pursue its development in a higher organization. Racial degeneracy also¹² may operate in a similar manner to climatic factors mentioned above.

latter causes may form important factors in the prolongation of the disease through several generations.

It is possible that the seed of the disease imported originally from the south of Europe, and from the French settlements of Canada, would have perished in more elevated and healthy regions. The habits of the Creoles of the Lower La Fourche, appeared to be temperate and simple; the education of many of the citizens appeared to be limited from the nature of the country, and the necessity of maintaining large families on small areas of land. It is evident, therefore, that under these circumstances, the contiguous settlements were often closely related by ties of friendship and blood. (Louisiana Board of Health Report, 1880.)

¹¹ Dr. Smith, of Tracadie, writes: "I have no reason to suppose that leprosy originated spontaneously in Nova Scotia from infected fish."

¹² The chief centers of goitre in Scotland were in the interior, Perthshire and east coast of Fife, the Kingcase lepers were in Fife. There are also centers of it in the southern counties (Mitchell, British Medical Chir. Rev., 1862), in the east of Wigtownshire and Kirkcubrightshire, in Dumfriesshire and Roxburyshire, in the west of Berwickshire, in the northern districts of the counties of Selkirk, Peebles and Lanark and adjoining parts of Ayr, and in the Isle of Arran (Blackie Reid). Wigtown, Kirkcubright, Dumfries and Ayr were centers of the disease sibbens. Arran is in the Hebrides.

Sibbens and goitre among the Scotch, and goitre and cretinism in the inhabitants of our Cordilleras, are evidences of racial degeneracy. Dwarfism and the cagots of the Pyrenees are merely stages in the dying out of a race. Leprosy is a disease of degeneracy.—A. S. A.

[NOTE.—Sibbens: See also E. Gilchrist, "An Account of a Very Infectious Distemper Prevailing in Many Places." Essays and Obs. Phil., Soc., Edinb., 1771, iii, 154-177. J. Rollet, Sibbens d'Ecosse. Dict. Encycl. d. Sc. Méd., Par., 1881, 3, s. ix, 522-526. Willemoes. Af handling om den i Skotland herskende Sibbens v. Syphilis insomium. Med. Hensyn til den Norske Radesyge. (Comparison of Sibbens with Radesyge.) Biblioth. J. Laeger. Kjøbenhavn, 1810, ii, 25-42. D. Wills, Remarks on Sibbens. Monthly J. M. Sc., Edinb., 1844, iv, 282-289. Also: Dublin Q. J. M. Sc., 1844, xxv, 346-354. W. Wright, Syphilis in Canada, as denoted by Sibbens. Med. Chron., Montreal, 1855, ii, 290-309. Wills refers to an article by Dr. J. J. H. (Edinb. Jour. Med. Sc. for 1826), where he attempts to prove that sibbens of Scotland and West Indian yaws are the same disease. "This disease" (sibbens), he says, "is analogous to frambesia of the fifteenth century." He thinks that the outbreak from 1483 to 1493 corroborates this opinion. "Sibbens and yaws of the West Indies are alike in whitish ulceration of tonsils, fungoid character of sores, a first attack probably giving immunity from a second, and their appearing to run a somewhat similar course in point of time. Mercury has a specific effect in sibbens."

Benjamin Bell's work on Venereal (1793) has a section on "Some peculiarities of form under which lues venerea has appeared in Scotland and Canada (called sibbens in the Highlands and yaws in Dumfries and Galloway). A soft, spongy excrescence, in size and color resembling a common rasp, which is apt to appear on all such parts as either become ulcerative or that are attacked with any kind of eruption; hence the name sibbens or wild rasp. This spongy substance may rise to a considerable height, nor can it be kept down by any of the common escharotics; if entirely removed it soon returns, unless the virus be removed by mercury." Wright thinks that button scurvy as observed in Ireland, and frambesia in the West Indies and Africa, are analogous affections. He thinks there is nothing national in the affection sibbens as it appears in the Scotch.

[NOTE.—Mr. E. Foster, of the *Daily Picayune*, New Orleans, La., has written me as follows: "There is little doubt that leprosy existed in this State before the arrival of the Acadians in 1765 (ten years after the so-called expulsion), but whether Elephantiasis Græcorum or Arabum there is some doubt. It is probable that during the twenty years which elapsed between their advent and the establishment of a leper hospital by Miro in 1785, the disease had spread to such an extent amongst the immigrants that such establishment became imperative? This is negative evidence to my mind. There is a belief that the disease was introduced amongst the Acadians of Lafourche by their compatriots who came from the West Indies, but of this I can find no confirmation. It is interesting to note, however, that Sloane mentions a case of 'Græcorum' in Jamaica at the end of the 17th century. That the disease should exist amongst the Acadians in New Brunswick and in Louisiana is a positive argument of weight, but at this late date it will be impossible to prove whether the statement of Dr. Pratz (1718) referred to the Yaws, Arabum or Græcorum. The Acadians of Louisiana, at least, are not an effete race by any means, and personally I do not think that leprosy is a sign of degeneracy. Goitre, cretinism and idiocy are different, but I can not find that there is any sign of either amongst the Acadians of Louisiana. As a class they are larger in stature than the Creoles, and while a large number of them may seem to be dull of intellect this can be put down to what I call it—hereditary business induced by the richness of the soil, of which you have merely to scratch the surface, scatter a few seeds and nature supplies the rest with a bountiful hand."—A. S. ASHMEAD.

A SUGGESTION THAT NATIONAL LEGISLATION PROVIDE FOR A MEDICAL EXAMINING BOARD TO CONFER A SPECIAL DEGREE IN MEDICINE AND SURGERY

AND THAT THEREAFTER THE STATES, THROUGH THEIR MEDICAL LICENSING BOARDS, SHALL LICENSE ONLY UPON THIS DEGREE.¹

Read before the San Francisco County Medical Society, Nov. 12, 1895. [Published in the JOURNAL of the AMERICAN MEDICAL ASSOCIATION by official request of the Society.]

BY C. E. FARNUM M.D.

DEMONSTRATOR OF ANATOMY AND ADJUNCT TO THE CHAIR OF ANATOMY, COOPER MEDICAL COLLEGE, SAN FRANCISCO, CAL.

That there is a plethora of medical colleges and of medical students and practitioners in the United States, is so well-known that it is unnecessary to make the assertion in this paper. That this condition does not exist in countries in which governmental restriction is exercised over the examining and licensing of physicians and surgeons is clearly shown by statistics giving the relative number of medical colleges, students and practitioners in proportion to population in the several countries of the world.

From an editorial published in the JOURNAL of the AMERICAN MEDICAL ASSOCIATION, dated March 24, 1894, it is said of the number of students attending the 136 medical colleges in the United States (109 regular medical colleges, 19 "homeopathic" and 8 "eclectic"): "At the sessions of 1885 the total attendance was 10,891 of which 9,245 were regular, 1,032 homeopathic, 614 eclectic. During the sessions of 1893, the attendance was 18,910, of which 16,759 were regular, 1,410 homeopathic and 741 eclectic. These figures show gains in eight years of 73.6 per cent. in the total attendance, 81.2 per cent. for the regular students, 30.6 per cent. for the homeopathic, 20.6 per cent. for the eclectics, an average of 9.2 per annum during the period. The average increase of population during the same period was less than 2.5 per cent. So that instead of being a diminution of students of medicine in relation to population, there is a relative increase nearly four times greater than that of population. As a matter of practical interest to the profession it may be noted that there is an average increment of nearly 6,000 new home-made physicians every year, and that while the population increased 24.8 per cent. during the decade 1881 to 1890, the number of newly graduated physicians increased 50 per cent. during the same period; last year, 1893, the increase was a trifle over 8 per cent." From statistics collected by F. W. Reilly, M.D., making interesting comparisons of the number of students attending medical colleges in the United Kingdom, France, Germany and the United States and Canada, and published in the same journal in the issue of Jan. 12, 1895, I quote the following:

"United Kingdom (Great Britain and Ireland), 8,696 total registered students between 1889 and 1893; for the year 1893, based on yearly accretions, 7,000; population, 37,000,000.

"France, total number medical students inscribed on the books of the Paris Faculty of Medicine for 1894, 5,144; population, 40,000,000.

"Germany, total number medical students registered for 1894, 8,684; population 50,000,000.

"United States and Canada, total number medical students in attendance sessions of 1894, 20,800; population, 70,000,000,

"Proportions: In the United Kingdom, 1 medical student to 5,286 of population; in France, 1 to 7,776 of population; in Germany, 1 to 5,757 of population; in the United States and Canada, 1 to 3,365 of population."

After reading these statistics we doubtless agree with the editor of that journal when in an issue of Dec. 29, 1894 he says concerning the increasing student classes, "Congress may put tariffs up or down, or abolish them entirely, may threaten currency legislation or railroad-pooling bills, or any other device for or against the prosperity of the nation, but here is one American infant industry that thrives apace and asks for no protection. What the struggling practitioner in the already overcrowded ranks thinks of it belongs to another category."

A government medical board upon whose examination alone can licenses to practice be granted, is perhaps the only means by which in the United States this increasing plethora of medical colleges and graduates can be relieved. It is only through national legislation that the medical colleges in the United States, or in fact in any other country, can be forced to adopt a uniformly high standard of medical education. Such a standard will certainly not be attained by the ununited and non-coöperative methods now pursued by the several medical schools of this country.

It can not be expected that Congress will ever take from the several States of the Union the right or power to regulate the licensing of physicians and surgeons; but national legislation can provide for a government medical and surgical examining board that could examine all applicants and to those who pass the examination confer a special degree with some proper title, such as "Fellow in Medicine and Surgery, United States of America." In order to maintain a high standard of requirements for passing this examination and keep this examining body free from political influences, a controlling majority of the members of this board should be selected from the medical staff of the United States Army and Navy. A degree from this board should be accepted as sufficient evidence of qualification or fitness for admission to medical positions in the Army or Navy. For the convenience of applicants in the several States, this examining board could periodically hold meetings in each State or district of the Union.

This government board having been formed for the purpose of examining applicants as to their qualification to practice medicine and surgery and for the purpose of conferring a degree or giving a governmental recognition of that qualification, the several States of the Union would then have a uniform standard upon which they could license physicians to practice, and each State could through its legislature provide that any person not already licensed to practice medicine and surgery in that State must first present a degree from the national board of examiners before he can obtain a license, the applicant's license then to be granted regardless of what medical college he has ever attended or whether he has or has not ever attended a medical college. By this plan the granting and the revocation of licenses to prac-

¹ This Board to be principally composed of and under control of the superior officers of the medical staff of the United States Army and Navy.

tice would still be reserved to each State, the government standard of qualification being the only one upon which licenses would be granted. With such a national examining board in existence, but a short period of time would elapse before all States and territories would license only upon certificates of qualification issued by this board or else permit to practice only those who could register a degree from this board.

In examining the last report of the Secretary of the Illinois State Board of Health, I ascertain that in only sixteen of the forty-nine States and territories in the United States is an examination for a license required of all applicants. The examining boards in these States are appointed by the governor or a local board of health or elected by a county or State medical society; in one State, Texas, they are appointed by judges of district courts. These sixteen States represent but a small proportion of the population of the United States. They are Alabama, Arkansas, Florida, Indian Territory (Cherokee Nation), Maryland, Minnesota, Mississippi, New Jersey, North Carolina, North Dakota, Pennsylvania, South Dakota, Texas, Utah, New York, Virginia and Washington. In the remaining thirty-three States, including the District of Columbia as one, the legal requirements for practice are either none whatever or a license granted upon some diploma, a registration of some diploma, or, in a few States, an examination in the absence of a diploma. At the present time, any licentiate in one State in the Union moving to one of sixteen States that now license only upon examination, would be put to the inconvenience of passing an examination in each one of these States in which he may locate, an experience which could be avoided should all States license upon a degree or certificate issued by a national examining board.

No "pathy" should be recognized in the personnel of this board. Since all who practice medicine and surgery, homeopaths and eclectics included, proclaim that they have studied and are familiar with regular medicine and use it in their practice, a degree from this examining board would be simply verification of their claims. If they want a special degree as evidence of knowledge in their preferred "pathy," their own college can furnish them with that. This board should recognize neither "pathies" nor diplomas nor any medical schools or teaching bodies. Homeopaths and eclectics, familiarizing themselves in therapeutics sufficiently to pass the examination before this board, certainly should be able to well understand what they term "comparative therapeutics" and perhaps make such use of their own therapeutic methods as would be in better conformity to their theory and more satisfactory to themselves.

This national board of examiners should be permitted to make its own rules and standard of requirements and exercise its own judgment as to how many and what subjects all the candidates shall be examined upon, the only restriction being that a degree or certificate of qualification shall be issued only upon examination. This would prevent interference through court processes with the proper and satisfactory performance of its duties.

What is suggested in the foregoing may be briefly stated as follows: 1, that national legislation provide that a national board, principally composed and under control of the superior officers of the medical staff of the United States Army and Navy, shall examine all

applicants as to their qualifications to practice medicine and surgery, and, to any one who successfully passes the examination, shall issue a certificate or degree as evidence of such qualification; 2, that thereafter each State legislature, at its option, may provide that its medical licensing board shall accept as evidence of proper medical qualification upon which to issue license only the degrees or certificates of qualification issued by the national examining board.

The national examining board and the State licensing boards would be entirely independent of one another, it being optional with any candidate to undergo an examination by the national board and optional with each State to adopt or accept as evidence of proper qualification to practice medicine and surgery, and upon which to issue a license to practice, the degree or certificate of the national board of examiners or, as at present, a degree from a local or foreign college or a certificate from a State examining board. However, should any State or States or all the States adopt the national standard of qualification for practice and issue licenses only upon certificates or degrees from this national examining board instead of it being optional with the candidate to appear before the national examining board, it will by the State be made necessary that he do this in order to obtain a license. In other words, the States would still reserve to themselves the licensing function and the right of revocation, but would adopt and accept only the national standard of qualification upon which to grant licenses.

The principal results that would follow from licensing physicians and surgeons upon no other evidence or certificate of qualification than a degree conferred by a national examining board under control of the superior officers of the medical staff of the United States Army and Navy, would be as follows:

1. The examining body will not be under the control of politics or of medical colleges, or of medical societies in which members of college faculties have a controlling influence.

2. A better and more uniform standard of qualification would be required. The granting of licenses upon diplomas from all kinds of colleges, both local and foreign, or upon examinations by boards of examiners elected by State and county medical societies or appointed by governors, as is done at present, certainly does not give as good assurance of proper qualifications as would a certificate based upon examination by the superior officers of medical staff of the United States Army and Navy. Who does not know that a college diploma, whether American or foreign, is not infrequently issued to those who are much more poorly qualified than is the average practitioner and to those whose qualifications would be inferior to one who had successfully passed examination by the medical staff of the United States Army and Navy? To the medical profession in foreign countries it certainly must seem peculiar that those who have degrees from European colleges can in this country be licensed upon degrees or diplomas that in the countries in which they are issued would have no legal recognition or would not be recognized by a licensing board or accepted as evidence of proper qualification for practice. It is a well-known fact that in many of the best foreign medical colleges, especially in Germany, attendance upon lectures or college curriculum is not obligatory, and that in applying for a degree of

Doctor of Medicine simply the passing of the examination is required, no other evidence whatever of previous study or attendance upon college curriculum being required. In other words, any person passing the examination in one of these universities can, without ever having studied or attended upon a college curriculum, get the degree of Doctor of Medicine, a foreign diploma, upon which most of the licensing boards in this country will now grant him a license to practice medicine and surgery, while in all American colleges an attendance upon the full college curriculum, extending over a period of four years in the best colleges, is required before a student can present himself for a degree upon which a license will be granted. So great is the American demand for a foreign degree or diploma rather than for a medical education obtained in a foreign college that it is very doubtful whether this custom of issuing degrees or diplomas upon examination alone will soon be corrected in the foreign universities which, while maintaining a high standard of actual college work, are equally as anxious to supply the American demand. If a degree in medicine, even from the best universities, is with good reason discredited by the German government and licensing boards, and also by some other foreign governments and licensing boards, there certainly should be the same reason for discrediting in this country that degree to the extent of also refusing to accept it as sufficient evidence of qualification upon which to issue a license.

3. The standard of requirements for graduation from medical colleges in this country, and perhaps also in European countries, would be increased as a consequence of provisions for a government examining board. In order to acquire such qualifications as would be required by this examining board and avoid the publicity of failure before a government board, students would attend only such medical colleges as give the best instruction and opportunities for study and have the highest standard of requirements for graduation.

4. The number of medical schools in the United States would greatly decrease, since students expecting to appear before this national examining board will not attend the colleges that do not give superior instruction and superior facilities for study.

5. Merited aid will be given to worthy medical schools that now require a high standard of education and desire to still higher advance the standard, since competition from low standard colleges will be eliminated. For this reason legislation favoring such a national board of examiners as is here suggested will doubtless be opposed by the low-standard college men.

6. The number of students beginning the study of medicine and of graduates engaging in its practice after a short period of study and without proper qualifications, would be greatly reduced, a higher and more uniform standard having in this an immediate effect.

7. This national standard of qualification would effect in many cities the consolidation of several medical schools now existing independently and endeavoring to outbid one another through a low standard of requirements for graduation, "not lived up to," but represented ostensibly to the public as a high standard.

8. It would make the practice of medicine and surgery more remunerative by lessening the number

engaging in its study and practice, consequently the number of medical colleges and the number of free clinics that have the medical colleges as an accepted excuse for their existence.

9. General recognition of the necessity for a high standard of medical education and an enforcement of such requirements would doubtless induce some of the best medical schools to be changed to post-graduate colleges, fortunately emphasizing the fact that what we now need are more post-graduate schools and a smaller number of medical schools for undergraduates.

For the benefit of colleges desiring to give proof of the claim that their professors are qualified as teachers, and, furthermore, that the graduates of all sorts of American colleges (regular, homeopathic and eclectic) should not, as at present, have the same standing or recognition when they enter European colleges, it might be well for national legislation to further provide that, any candidate having first passed the general examination or possessing a license from any State, may at any time, upon passing a special examination in any subject or department in medicine or surgery or in sciences cognate thereto (as anatomy, physiology, chemistry, bacteriology, pathology, general surgery, etc.) obtain another degree or certificate of proficiency showing that he is qualified to teach or become a professor in that subject or department of science. The students who enter college to study medicine and surgery and the public who employ them as graduates and practitioners educated in these colleges are certainly entitled to that much assurance or proof of proper qualification on the part of medical instructors, and the faculty of any medical college that actually desires to advance the standard of medical education and the standing of the college itself should certainly hail with delight any plan by which to separate among medical colleges the chaff from the wheat, by which to prove that what is proclaimed in college catalogues and at commencements from the rostrum about thorough instruction is not mere bombast and advertisement.

THOUGHTS ON VITAL RESISTANCE TO DISEASE—IMMUNITY, NATURAL AND ACQUIRED.

Read in the Section on Physiology and Dietetics at the Forty-sixth
Annual Meeting of the American Medical Association,
at Baltimore, Md., May 7-10, 1895.

BY G. W. FINLEY, M.D.

HARMONY, IND.

We occasionally observe individuals whose state of health, physically and mentally, seems so thoroughly perfect that they can and do pass through epidemics of virulently infectious disease unscathed. We observe a far larger number who prove themselves, for the time being at least, impregnable to exposure or even inoculation with germs of certain contagious diseases, and who yet fall easy prey to other diseases on slight exposure. The latter class are protected only as to certain germs, either by the fact of having previously experienced an attack of the given malady, or by some inherent quality in their own organization. In this consideration, the possible protection afforded by some extraneous circumstance, such as approximately perfect sanitary surroundings or the influence of chemic disinfectants, is supposed to be excluded.

This difference in susceptibility to infection, shown by different races of people, by different individual subjects under what is apparently the same environment, and by the same person at different times of life, must be accounted for on some physiologic principle. If that peculiar physiologic state constituting immunity to disease can be accurately determined, may it not be cultivated and induced for universal prophylaxis of disease in the twentieth century, as well as to suggest the most effective treatment of unavoidable cases, in the very practical present? We find that the various normal secretions and excretions of the body are essentially antiseptic in their nature and functions; that is, that while they carry off the waste products of the animal economy, they prevent the decomposition of the same until it is well out of the way, and they at the same time stand guard against the introduction of foreign or deleterious agencies. Not that these excretory fluids in their normal state are free from microorganisms, for, as a rule, they abound in the evidences of such life, but always of a fixed type. Interference with these secretions, either by mechanical violence, by internal drugging or even by the substitution of artificial sterilized fluids, is found to favor the reception of disease germs.

Through defective elimination of effete materials by the various excretory organs of the body, as the emunctories of the integument, the uriniferous tubules of the kidneys and the imperfect oxygenation of venous blood in the lungs, the circulatory system is heavily loaded with dead freight. All the elements necessary for the development of a greater or less degree of septic auto-infection are thus present, and the fire will rage unless it be effectually quenched by some vital resource ready at hand. If the powers of natural self-preservation prove at all equal to their task, however, we find that decomposition and absorption of resulting poisonous ptomaines will be delayed until elimination can at last be completed without harm. If one channel of elimination be effectually blocked, other channels will be called upon to do double duty, temporarily, and the work be accomplished before organic necrosis can occur as a result of the presence of foreign or poisonous substances.

We can aid the natural processes of elimination by many well-known remedies of internal, external and eternal application. Unfortunately, however, many of these empirical remedies leave the delicate organism thus stimulated weaker in action than before, thus finally tending to destroy one of nature's means of defense against the inroads of disease. In attempting by therapeutic measures to assist nature in the restoration of healthful functions, we must exercise particular care to avoid that extreme stimulation which is rather irritation and which, on reaction, paralyzes natural functions. We should also strive to add, if possible, to the natural antiseptic virtues of the excretory fluids to be manifested as the excretions clear the outlets of the body.

But whether it be dead material of the body's own waste, or toxic ptomaines produced by disease germs, natural resources, chief among which appears to be the multinuclear white blood-cell, at once make the attempt to neutralize the ill effects and to clear it away as quickly as possible. Unless suddenly overpowered by force of numbers of the invading foe, these natural resources of defense in the normal blood current will render inert, or expel from the

system, whatever pathogenic germs may be introduced into its circulation. In this conflict between life and death, when life is gaining the victory and convalescence is established, the microscope reveals the fact of an enormous increase in the comparative number of white blood-corpuscles or leucocytes. This peculiar state of the blood is observed to be a constant and well-marked feature of all convalescence from acute disease. The question has occurred to the thoughtful physician that if leucocytosis could be artificially induced in an acute attack of disease, would not complete convalescence also occur early and before the patient had become debilitated by the ravages of the disease? Nay, might not the infection be prevented from developing at all, if nature's own means of defense in the leucocytes or phagocytes could be reinforced at the very beginning of the attack, or, still better, before the exposure to the deadly infection.

The ancient operation of transfusion of blood and other saline fluids, was a step in the dark, but a rational one, and in the direction of light. When applied to cases of marasmus and anemia, and where the care taken by the surgeon amounted to practical asepsis, the results were often very gratifying. The remarkable growth of the distinctly modern idea of sero-therapy may have owed its origin in some remote degree to the records of observations on transfusion. It is found that the immunity inherent to certain species of animal life may be borrowed and transmitted at will to other warm-blooded animals by means of injection of blood serum. Then, if natural immunity can be so readily and surely transferred to another, an easy and logical step leads us to the consideration of the cultivation and universalization of acquired immunity. Concerning a limited number of the best known and most dreaded infectious diseases, this beautiful dream of the bacteriologist now seems to be practically realizing. Behring, Roux and Aronson have identified their names with the work of producing artificial immunity to diphtheria by the use of a specially prepared blood-serum taken from an animal almost immune to the disease and rendered totally so by a process of cultivation of attenuated germs in the animal's system. These men, as also, in other parts of the world, Tait, Ehrlich, Pasteur, Koch and Kitasato, sought to place in tangible and practical form what had existed as a vague, but gradually clearing, theory among scientists during the last two decades.

Granting that pure blood serum contains the toxalbumin so effective in the animal economy during life, the question arises, Can its essential principle be isolated and preserved in a form less bulky than the serum and yet safe and effective for the physician's use in combatting, mitigating and even preventing the ravages of deadly infection? Our own original investigators, Vaughan, McClintock, Sternberg and others have demonstrated that it can be. Proceeding on the line of thought peculiar to the theory of cellular pathology, these earnest scientific philanthropists have sought and found a nuclein acting as the foundation of all Nature's defensive and offensive operations against the toxic ptomaines generated by pathogenic life. If a specific modification of the natural nuclein results from the experience of the body in undergoing disease it must be either by a gradual process of education of the individual cells to the end of more effective resistance to the germ of that

disease, or the multiplication on a grand scale of similar immunizing cells, the protecting influence of which may last for a term of years, if not for the remainder of the subject's lifetime.

We quote Professor Vaughan, of Michigan University: "A virus being introduced by any means into the living organism, the spleen is stimulated to action, and secretes a nuclein which is carried, partly in solution, partly in the form of multinuclear cells to the invaded part of the body, and the poison is converted into the nuclein coming into contact with it, or is otherwise rendered inert. Later, a larger quantity of the identical virus may be introduced, and now the spleen will act more promptly and energetically than before. This promptness and energy of action are increased by exercise until finally, an amount of virus sufficient to kill an animal, whose spleen has not been subjected to this training, may be taken without the slightest ill effect."

Not only is it proven that nuclein from blood serum possesses antitoxic and germicidal powers, but also that a nuclein isolated from pure cultures of the yeast plant has the same decided germicidal and antitoxic powers when brought in contact with germs of diphtheria. So, in the peculiar cells characterizing the normal tissues and glandular structures of the animal economy, as well as in those of the protean forms of vegetable growth, may we not find the various nucleins requisite for reinforcing the inadequate natural powers for defense of human life against the powers of death?

Dr. Bleyer of New York, Dr. Aulde, of Philadelphia, and others have found in practice that "nuclein possesses, in addition to its specific action, a dynamogenetic power, increasing the vigor of the central nervous system." It seems to produce and hold the beneficial effect of a pleasantly stimulating electric current. Indeed, it is a very probable explanation of physiologic action of all remedies, including the assimilation of all food and drink, that the well-known selective affinity of living cells, is in fact an electrical attraction, the one for the other, due to opposite polarity of the cell elements. The condition of ideal health is one of the most nearly perfect electro-equipoise, the happy subject of this condition being so well balanced that he is, Diogenes-like, composed in mind and physically fearless. The poor old philosopher in his tub, prizing the sun-bath above all royal favor, was right, though cynical, in declining the king's offer of the luxuries of wealth and asking simply that earthly royalty stand aside that the great source of all electric life-force might shine upon the bather.

Natural immunity may perhaps be most expected in the midst of ideal sanitary surroundings, and in those of reasonably regular habits, temperate in all things, yet of that sanguine temperament knowing no such words as discouragement or shrinking from duty. Trained nurses and busy physicians are familiar examples of immunity and longevity in this class. But, alas! the rank and file of modern population with inherited weaknesses, unsanitary homes, careless and vicious habits of life, are found sadly in need of artificial help in order to begin to help themselves on these lines. When we can offer them a protecting proteid nuclein, in addition to prophylactic sunlight and fresh air, cheerful and pure surroundings, judicious exercise of body and mind, together with sterilized food taken in moderation, may we not

confidently hope to see the insurance actuaries' table of the expectation of human life raised to the level of at least a round hundred years?

The writer has, during the past few months used, with much gratification, a nuclein preparation in the treatment of cases of pernicious anemia, septicemia and general marasmus. It has seemed to offer most excellent assistance in the abortive treatment of incipient tuberculosis, but time, and multiplied cases must decide as to the sure or uncertain foundation of this hope.

SOME RECENT DISCOVERIES IN REGARD TO THE MODE OF ACTION AND CHEMISTRY OF COD LIVER OIL.

Read in the Section on Materia Medica and Pharmacy at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY F. E. STEWART, M.D., Ph.G.

DIRECTOR OF THE SCIENTIFIC DEPARTMENT OF FREDERICK STEARNS & CO.

The mode of action and chemistry of cod liver oil has long been a subject of controversy, one side contending that the oil from the liver of the cod is "merely a nutritive agent having the advantage over other fats of a readier entrance into the system, and a more ready assimilation," and the other side contending that, "on account of some peculiar principle or principles it contains, cod liver oil exercises a stimulant and alterative influence on the processes of assimilation and nutrition, thereby aiding in the production of healthy tissue." It is a well-known fact that fat itself, when taken as a food, does not necessarily fatten, and that the fat of our bodies is derived from a conversion of proteids and carbohydrates, fat itself playing a very insubordinate part in the process. This is strikingly illustrated by the various diets recommended for the treatment of obesity. Ebstein considers that the formation of fat is chiefly dependent on the simultaneous free use of carbohydrates, but that the consumption of fats has little or no effect in the storing of fat in the body. He believes that the presence of fat in the food prevents the storing of fat in the body because it produces a feeling of satiety or satisfaction, and so leads to the consumption of less food; and also, by diminishing thirst, lessens the desire for fluids, the ingestion of the latter favoring the laying on of fat. Dujardin-Beaumetz points out the fact that Hypocrates anticipated Ebstein, and quotes his advice to the obese that they should eat fat on account of its satisfying effect and its virtues of lessening the consumption of food. Oertel advocates the use of fat for the treatment of corpulency, although he allows more albumin and less fat than Ebstein. Foster and other physiologists teach that the part played by fat in nutrition is that of furnishing fuel to the system for the production of energy, and that the fat stored in the body is manufactured by the body itself, principally from the proteids and carbohydrates, the fat playing an insubordinate part.

When cod-liver oil is taken, however, a rapid increase in the weight of the patient is often noticed, owing to the stimulating effect it has upon the process of metabolism. This is not a simple storing of fat but an increase in the muscular tissue as well. Some patients, however, gain rapidly in strength, without adding to their weight, especially when their body weight is not much below the normal. All these arguments are in favor of the view that the oil con-

tains some peculiar principle or principles which augment the appetite and stimulate the formation of tissues. Since 1822 chemists have endeavored to ascertain what principles exist in cod liver oil to account for its alterative effect. They have succeeded in isolating, from time to time, some fifty different substances from the oil, several of them being well-known alteratives. According to the United States Dispensatory, "From an analysis of the oil by De Jongh, it appeared to contain a peculiar substance named *gaduïn*: oleic, physetoleic, palmitic, stearic and myristic acids, with glycerin; butyric and acetic acids; various biliary principles: iodine and traces of bromine. The formula of *gaduïn*, according to De Jongh, is $C_{35}H_{70}O_6$. Dr. Luck has found a peculiar fatty acid in turbid oil, which he names *gadic acid*, and the same is obtained from clear oil by saponification. (*Neues Jahrb. für Pharm.*, vi, 249.) As, however, about 70 per cent of cod liver oil is olein, and about 25 per cent. is palmitin with some stearin, *gaduïn* and *gadic acid* do not constitute a very important factor. Indeed, Flückiger considers their very existence doubtful. M. Chapoteau¹ claims to have discovered in cod liver oil a crystalline substance, *morrhuel*, containing phosphorus, iodine and bromine. He states that the brown oil yields from 4.5 to 6 parts in 100, the straw-colored from 2.5 to 3 parts, and the bleached oil from 1.5 to 2 parts. (*A. J. P.*, 1886, p. 19.) According to Dr. Lafarge (*Progrès Méd.*, Feb. 20, 1886; also process for preparing), this substance represents the peculiar medicinal properties of cod liver oil, and in tuberculosis and allied diseases may be given in capsules containing from three to five drops as about equivalent to one drachm of cod liver oil. By reaction with ammonia in distillation the oil yields a volatile alkaloid, *propylamin*, C_3H_7N , which has a strong pungent odor, recalling that of herring pickle, of which the same alkaloid is an ingredient. No other official fatty oils yields a similar product. (See *A. J. P.*, xxiv, 343.) Messrs. Gautier and Mourgues have obtained from cod liver oil the leucomaines butylamin, amylamin, hexylamin and hydrodimethylpyridin, and two fixed bases, *asellin* ($C_{25}H_{52}N_4$) and *morrhuin* ($C_{19}H_{37}N_3$). *Asellin* was found by its discoverer to be relatively feeble physiologically; *morrhuin*, of which about two milligrammes are believed to exist in a tablespoonful of ordinary cod liver oil, is affirmed to have the properties of exciting the appetite and acting as a powerful diuretic and diaphoretic. Some have been disposed to ascribe the virtues of cod liver oil to its iodine and bromine; but these are in too small proportion for much effect, and the oil has produced results which have never been obtained from iodine and bromine themselves. The presence of iodine can not be detected by the usual tests. It is necessary to convert the oil into a soap, and to carbonize this, before it will give evidence of iodine. The proportion never exceeds .05 per cent., or 1 part in 2,000, and it is by no means certain that iodine is always, if ever, present in pure oil. The proportion of iodine present has been recently investigated by E. C. Stanford (*Pharm. Jour.*, xiv, 353), who found it to be extremely minute, ranging from .000138 to .000433 per cent., with an average of .000322 per cent. The oil is capable of dissolving a larger proportion of

iodine; and, if any specimen contains more than .05 per cent., there is reason to suspect that iodine has been fraudulently added.

According to Gautier² and Mourgues³ different factors unite in producing the undeniable reconstructive activity of cod liver oil. They state that "In the actual state of our knowledge upon the constitution of this celebrated medicament and upon the properties of the definite principles which enter into its complex composition it appears to owe its therapeutic efficacy and its powerful reconstructive action to the following group of agents:

1. "Cod liver oil acts by the fatty bodies, which are easily assimilated because of the slight acidity and partial saponification which can be attributed to the hepatic ferments; also because of the presence of biliary principles in solution, which render emulsification extremely easy, especially in the digestive tract, where it aids the action of the pancreatic trypsin. These easily digestible fats (namely, the fatty bodies already referred to) are ready for immediate assimilation, their ingestion resulting in storing the body with protective agents or reserve material to be utilized as needed by the economy to supply fuel for producing heat, etc."

2. "These oils act as energetic builders of tissue by their richness in phosphates, phosphoglyceric acid, lecithin and phosphorus in other organic states. It is known that under the last three forms the economy assimilates phosphorus most easily. This element is indispensable to the production of the nuclein of the cell and therefore to the proliferation of the cells. It is also known that these same forms of phosphorus preside more particularly over the activity of the highest cells in the scale of life; cells of brain, egg and embryo."

3. "The basic principles, already referred to, stimulate the nerve system, augment the appetite, accelerate intro-organic oxidation, and increase the secretion of urine and sweat. *Morrhuin* is the most important of the matters found in the extract. It is a powerful stimulant of the functions of nutrition and assimilation promoting metabolic changes. It produces a rapid circulation of the extractive residues of cell life toward the excretory organs, where they are eliminated, provoking in this way, indirectly, a powerful movement of assimilation (anabolism) correlative of the losses consequent upon the inverse movements of de-assimilation (katabolism). This is considered as proven by the super-excitation of the appetite of animals brought under its influence."

Under the caption, "Cod Liver Oil and Chemistry," a book has recently (1895) appeared, written by F. Peckel Möller and published by the firm of Peter Möller, the latter being the title of a well-known cod liver oil manufacturing establishment, whose office

² Armand Gautier, born 1837, Doctorat à Montpellier 1862, Professeur à la Faculté de Paris 1871, was, on the death of Chevreul, elected a member of the Section of Chemistry of the French Academy of Sciences to fill the vacancy thus created. This celebrated savant is distinguished for his work on the leucomaines. The first attempt at the systematic study and generalization of the basic substances found in living tissues was made by Gautier, who applied to them the name of leucomaines, a term derived from the Greek, signifying white of egg. Under this name he included all those basic substances which are found in animal tissue during normal life in contradistinction to the ptomaines, which are products of putrefaction. Gautier is of the belief that leucomaines are being formed continually and incessantly in the animal tissues side by side with the formation of urea and carbonic acid; and at the expense of the nitrogenous elements.

³ Les Alcaloïdes de L'Huile de Foie de Morue par Armand Gautier, membre de l'Institut, Professeur à la Faculté de Médecine de Paris, et L. Mourgues, Préparateur particulier au laboratoire de M. A. Gautier, Paris, G. Masson, Editeur. C. Braire de L'Académie de Médecine, 120 Boulevard Saint Germain, 1890.

¹ M. Chapoteau describes *morrhuel* in the following language: "An amber brown, bitter, aromatic liquid partially crystallizing at a low temperature, consisting of the free oleic acid of the oil, alkaloid- and subtle combinations of sulphur, iodine, bromine and phosphorus."

is located at 43 Snow Hill, London, E. C., and at Christiana, Norway. This book is for the purpose of exploiting cod liver oil manufactured by a new process which has been patented by Peckel Möller. This authority claims that, "The therapeutic action of cod liver oil is one entirely its own." The "real value of the remedy lies in the fatty acids which it contains, in the form of glycerids." According to the researches of his chemist, Mr. Heyerdahl, cod liver oil contains no olein or stearin, but consists of several glycerids, 40 per cent. of the oil being made up of therapin and jecolein, the list of glycerids consisting of one or more unsaturated acids belonging to the same series, but hitherto unknown to chemists. Möller's patent process consists of preparing the oil in an atmosphere of carbon dioxide to prevent the glycerids from being acted upon by the oxygen of the air and forming hydroxy-acids. He claims that the eructating of cod liver oil is due to the presence of these hydroxy-acids, and that their formation is the real cause of the rancidity of the oil. For the purpose of diminishing the demand which has recently greatly increased for extracts made from cod liver oil, and containing the principles to which its alterative effect has been ascribed, Möller attacks in a savage manner those who are interested in advocating the various extracts referred to, claiming that all the substances found in the oil by eminent chemists, except the fatty matter, are the essence of rotten livers and are due to putrefaction. Several other houses who are exploiting the plain oil and preparations of the same, such as emulsions, etc., have joined forces with Möller for the purpose of driving out the extracts such as morrhual, jecorol, etc., made from cod liver oil or from the cod livers themselves.

A field in which there is so much controversy is surely an inviting one for original investigation. The following pages are devoted to a report of investigations in this field under my own direction. We⁴ commenced with a careful inspection of the methods of preparing the oil, both in this country and in Norway. Preliminary to this, however, we corresponded with the leading manufacturers of cod liver oil in the world,⁵ and accumulated as much information as possible on the subject. Guided by the information thus acquired we commenced operations by going out with the fishermen on the fishing boats, off the coast of Massachusetts, and inspected their methods of catching the cod, collecting the livers and preparing the oil. After watching these operations we concluded to try some experiments in cod liver oil manufacture ourselves. Accordingly we rented a room and fitted up a laboratory for the purpose. After finishing our experiments at the fisheries

we collected some fresh livers, preserved them in alcohol, and shipped them to our laboratory in Detroit for further experiments. The results of these experiments were surprising and are so different, in some respects, from the information furnished us by the standard text-books, and so completely disprove the position of those who traduce the extracts made from cod liver oils and from the livers, that we consider them of sufficient importance to bring before the ASSOCIATION.

The principal cod fisheries of the world are seen at the Islands of Lofoten, off the coast of Norway. A great many cod are also caught off the coast of Iceland. In North America we have the Newfoundland and New England fisheries. Codfish are also taken on the banks of the British Islands, but not in commercial quantities. Russia sends more or less into the market, and a fine quality of cod liver oil is now made in Japan and marketed by Cocking & Co., of Yokohama. The Lofoten Islands form part of an extensive group of islands stretching down the Norwegian coast, numbering probably several thousand. The name Lofoten Islands is applied to the four islands forming the apex of the entire group, although officially only their southeasterly shores, facing Vestfjorden and the mainland, bear that name. The Lofoten Islands lie in the Arctic circle between latitudes 67 and 69, and are separated by narrow sounds, the islands themselves being covered with great snow-clad mountains, and giving some of the grandest scenery of the world. The supply of fish in these regions is something perfectly enormous. To illustrate this a story is told of how a shoal entered one of the fjords of East Vaago early in January, 1887. The fishing boats numbering 2,500 soon congregated at the spot and were successful in catching over thirteen millions of fish, this number, however, being a mere nothing as compared to the total in the shoal. The number of fish in this shoal was estimated to be about ten thousand million, and when it is considered that this shoal was only one out of possibly hundreds of shoals on the banks, the number of fish are beyond computation. The female codfish produces every year about one hundred thousand eggs for each pound of its weight; so that on an average each fish is responsible for a family of one million two hundred thousand fish every season. Only for inroads made upon the young fry by the whale and other denizens of the deep, the entire ocean beds would be completely choked with codfish in a few years. The output of the Norwegian fisheries, all told, is between forty and fifty millions of fish annually, yielding between fifty and sixty thousand barrels of oil.⁶ When to this is added the output of all the other cod fisheries of the world, the amount of cod liver oil manufactured in a year is simply enormous. Much of the oil, however, is used in the arts, being extensively employed by the tanners, etc., and only part of it is used medicinally. The methods of preparing the cod liver oil are the same in principle in all parts of the world. The pale yellow oil is prepared by submitting the livers to a jet of steam let into a conical vat, that has been filled with the fresh livers, for half an hour. The oil is filtered warm from the melting vat. The stearin is then separated by refiltration at a temperature somewhat below the freezing point. The various varieties of brown oils are prepared by exposing the livers to the heat of the sun, which expands and

⁴ I do not use "we" editorially, but in reference to our Scientific Department, which consists of F. E. Stewart, M.D., Ph.G., director; chemistry, C. C. Sherrard, Ph.C.; materia medica, L. H. Gardner, Ph.C.; pharmacognosy, F. H. Frazee, Ph.C.; therapy, F. E. Stewart, M.D., Ph.G.; botany, W. G. Rankin, Ph.C.; pharmaceutical assaying, J. L. TeGarden, Ph.C. Much of the chemie work has been done by Professor Sherrard, who had also associated with him Prof. J. O. Schlotterbeck, in charge of the department of pharmacognosy and materia medica of the University of Michigan. Sherrard and Schlotterbeck have worked together part of the time, and at other times have worked separately for the purpose of verifying each other's work. We have also to thank Prof. A. B. Prescott, Dr. C. D. Morris, assistant to Dr. Novy, and other members of the faculty of the University who have aided us in verifying our observations. The credit for the work, therefore, should be given to the Scientific Department of Frederick Stearns & Co., aided, as aforesaid, by members of the staff of the University of Michigan.

⁵ The manufacturers with whom we corresponded relative to the method of preparing cod liver oil included Isdahl & Co., Bergen, Peder Devold, Aalesund, Norway; Joh. Rye Holmboe, Tromsø; Foh. V. Borthen, Trondhjem. Cocking & Co., Yokohama, Japan; and the leading manufacturers of cod liver oil in Newfoundland and New England.

⁶ Cod Liver Oil and Chemistry. F. Peckel Möller, Ph.D., London, 1895.

bursts the oil cells. The first oil that floats to the top of the cask is quite pale and is known as raw medicinal oil. The second skimming is rather yellow and with a strong taste and smell, and is the light yellow oil employed for industrial purposes. The third or last skimming is a dark brown oil with a very strong smell and disagreeable taste, and is used exclusively for tanning purposes. It is generally supposed that the brown color of the darker varieties of oil is due to the products of putrefaction. This, however, we find not to be the case. It has also been charged that many of the substances found in the oil, to which its therapeutic efficacy has been ascribed, are also the products of putrefaction. This has been applied particularly to the leucomaines discovered by Gautier and Mourgues in the oil, the opponents of these scientists contending that the organic bases referred to, instead of being formed during the life of the fish, are ptomaines or cadaveric alkaloids resulting from putrefying livers. While it is true that several of the substances found in the oil are undoubtedly ptomaines, such for example as propylamin, to which the marvelous virtues of the oil have been ascribed by some of the best writers, yet we find that the bases discovered by Gautier and Mourgues occur in the fresh liver taken from the live fish. This fact has been noted by Bouillot as well as ourselves, and is true without question, as will be more apparent when our experiments are described in detail. The largest manufacturers of cod liver oil in the world is the firm of Isdahl & Co., Bergen, Norway. Their integrity is beyond question, and their well-known Midnight Sun brand of pale straw-colored oil commands the highest price of any of the cod liver oils on the market. In response to our letter making inquiry in regard to the manufacture of cod liver oil they state, under the date of Sept. 5, 1894, as follows:

In reply to your favor of the 8th ult. in relation to our light brown cod liver oil, we beg to inform you that for more than thirty years our firm has made a specialty in the way we prepare it of a sweet-tasting, light brown medicinal oil. It is quite a natural oil, which obtains its dark color from the length of time it remains on the livers, as we use only selected livers in its preparation. The ordinary brown cod liver oils to be got in our markets are prepared from the remainders of the livers after the natural yellow-colored oil has been skimmed off, and are only fit for tanning purposes. After this explanation you will understand that the light brown cod liver oil which we prepare has the same active medicinal principles as any other cod liver oil, and it may be still richer than any of them in alkaloids. We believe that its taste is more pleasant than the flat and insipid taste of the straw-colored oil, and we know from experience that a great many people for this reason give it the preference. This variety of oil may be sold under the title of Isdahl's Light Brown Lofoten Cod Liver Oil. Of course no American house has more right to the title of 'Lofoten Oil' than anybody else, although it is right to lay stress on the title Lofoten Oil, as the best oil produced in Norway comes from that district. We prepare our special brand of light brown cod liver oil from selected Lofoten cod livers only.

EXPERIMENTS ON COD LIVERS AND COD LIVER OIL.

The following experiments were undertaken for the purpose of proving that the color of cod liver oil is not due to a putrefactive process occurring in the livers from which it is derived and also for the purpose of proving that the 5 per cent. of extractive matter found in the oil is not putrefactive in its origin.

Experiment 1.—The fresh liver of a cod was taken and a section of it examined under the microscope to see whether there were any bacteria present. It being determined that bacteria were not present, incisions were now made in the liver and the oil

was allowed to exude spontaneously. The oil thus derived from the fresh liver was of a pale straw color.

Experiment 2.—The liver of a cod was exposed to the air until, under the microscope, the presence of bacteria was determined. Incisions were then made in the liver and the oil that exuded was of a pale straw color as before.

Experiment 3.—A batch of fresh livers was taken and examined by the microscope to prove the absence of bacteria. This batch of livers was now placed over the water bath at a temperature of 50 to 60 degrees C. for seventy-two hours. Every twenty-four hours examinations were made of the liver with a microscope to see whether or not bacteria were present. During this time the following changes were observed to occur in the liver substance: The parenchyma commenced to disintegrate and became a pul-taceous mass. During this process of disintegration the color of the liver parenchyma changed gradually through the various shades of brown until it became almost black. The oil remaining on the livers little by little took up this coloring matter and were darkened in proportion. By this means we were enabled to obtain cod liver oils from the same batch of livers of every shade of color on the market, simply drawing it off from time to time when the desired shade of color had been reached. While conducting experiment 3 the liver was examined from time to time to ascertain whether any bacteria were present, and during the entire time, from the beginning to the end of the experiment, no evidence of bacterial action was observed. For the purpose of having our observations verified, we sent specimens of the livers we were working on to the University of Michigan, and there had them examined with a thirteen hundred power oil immersion, and also had cultures made, the results being entirely in accordance with our observations in Detroit.

It is evident from Experiments 1 and 2 that the presence of bacteria does not determine the color of the oil, as a pale straw colored oil can be made from livers containing bacteria, as well as from those free from germs. Professor Sherrard mentions that he has seen at the New England fisheries light colored oil exuding from livers far gone in decomposition. Experiment 3 shows that oils of all the different varieties of color found on the market may be manufactured from fresh livers without the intervention of bacteria.

The next series of experiments were for the purpose of determining the presence of the leucomaines⁷ of Gautier and Mourgues in the various samples of the oil just manufactured. Their presence was easily demonstrated in the samples. The pale straw-colored oil contained but a small amount. The light brown oil contained a larger proportion than the darker oils. From this and other experiments which we have carried on with samples of oil made by different manufacturing houses and by close study of our own processes, we infer that in the preparation of the light brown oils a larger proportion of the leucomaines is found than in the pale oils or the darker varieties, for the reason that in the former case the liver parenchyma containing them is not disintegrated while in the latter instance the long continued

⁷ The process for determining the presence of the basic substances discovered in cod liver oil by Gautier and Mourgues is published in their monograph entitled, "Les Alcaloides de l'Huile de Foie de Morue."

action of heat has resulted in the decomposition of these organic bases. In our investigations many hundreds of samples of cod liver oil from every known commercial source have been analyzed. With the possible exception of cod liver oil prepared by Peckel Möller's new patented process, which we have not examined, we find that all the cod liver oils on the market contain more or less extractives, including the organic bases of Gautier and Mourgues, and that, while the dark brown oils contain more extractive matters than the light brown oils, yet the former are richer in the leucomaines than the latter. The probable reasons for this have just been stated.

The question naturally arises, What is the reason for the change in the color of the livers when exposed to the action of light and air. This subject is one requiring further investigation. Prof. A. B. Prescott, of the University of Michigan, with whom I talked on the subject, suggested that it might be a process of oxidation. That it is not due to action of bacteria is evident from what has already been said. The change in the color of the livers may be due to the same process that darkens the surface of freshly cut meat or gives to dried beef its rich brown color. A freshly cut apple darkens on exposure to the air. The dark brown color of opium is in strong contrast to the milky color of the fresh juice of *papaver somniferum*. Prof. Dolbear (as quoted in *Food*) says that the tanning of the skin, the darkening of newly laid shingles, and the coloring of apples and other fruits, is all a "photographic process."

That cod livers readily putrefy is not true. Even when exposed to the atmosphere for some time no bacteria appears in them. Just how long they can be thus exposed we have not yet determined. It is well known that bile processes some antiseptic qualities. As Foster says, "Out of the body its presence hinders various putrefactive processes; and when it is prevented from flowing from the alimentary canal, the contents of the intestines undergo changes different from those which take place under normal conditions, leading to the appearance of a variety of products, especially of ill-smelling gases." The antiseptic power of the bile is said to be due to the presence of glycocholic and taurocholic acids. It is evidently due to the presence of bile acids that the livers are not readily decomposed when they are exposed to the air. Carvalho and Pachon (*Archives de Physiologie*) have recently reported the results of their experiments on a dog deprived of his stomach. Among other things it was found that the dog thoroughly digested rotten meat, the same as a healthy dog. This is accounted for by them by the great antiseptic value of either the bile, or the intestinal fluids, or that the liver, spleen and perhaps other organs, are capable of destroying large amounts of ptomaines.

It is evident from the above experiments that the information in regard to the chemistry and manufacture of cod liver oil in our text books is, to a certain extent, erroneous and should be revised. It is also evident that all of the substances found in cod liver oil are not the products of putrefaction, as has been claimed by those interested in exploiting the plain oil and its preparations. It has been demonstrated that cod liver oil contains certain leucomaines and organic bases which, upon physiologic examination by their discoverers, Gautier and Mourgues, proved to be powerful stimulants to tissue metabol-

ism. It has been shown that fat itself has no such stimulating properties, and it is therefore reasonable to infer that this effect is due in a greater or less degree to the presence of the organic bases referred to. Other leucomaines exist which possess very similar properties. The leucomaines creatin and creatinin for example, found in lean meat, extract of beef, etc., are stimulants to the processes of tissue metabolism, and are now considered by Foster, and other physiologists, necessary ingredients of the diet, their office being to assist in the assimilation of proteids. The mistake has been in supposing these extractive matters to be nutrients. When it was proved that they were stimulants only, a reaction against them occurred, and the profession made a serious blunder in dropping the use of bouillon, beef tea, extract of meat, etc. When employed with a proper diet, consisting of the requisite quantities of proteids, carbohydrates and fats, they are powerful aids to the appropriation of food in tissue building. Further experiments in connection with the work on cod liver oil should be undertaken to demonstrate whether we are not making another mistake by employing oils from which the extracts referred to are left out. We have demonstrated that they are not necessarily the products of any putrefaction and that oils can be made, rich in extractive matters, from cod livers in which bacteria take no part. If it is proved that Isdahl, De Jongh, and other manufacturers of the light brown oil, are correct, and that their virtues are superior to the pale straw-colored varieties on account of the presence of the leucomaines of Gautier and Mourgues, and other active principles not found in the pale varieties, then methods for standardizing cod liver oils should be adopted for the purpose of securing a proper proportion of these substances therein. Further experiments should be made with the extracts, upon tissue building, in connection with the various classes of food. There are good reasons to suppose that in a large number of cases other fats may be substituted for the disgusting fat of the *gadus morrhua*, the same to be taken in conjunction with these extracts. Butter, cream and the fats of meats, etc., are much more agreeable than the fat of the cod liver, and, when combined with the powerfully stimulating extractive matters derived from the fresh liver of the cod, may prove valuable substitutes for cod liver oil. Morrhuol, one of the extracts made from the oil, has already acquired quite a reputation, and, if properly employed in connection with the right kind of diet, might prove still more efficacious. We manufactured some of the extract from the oil, by the process recommended by Gautier and Mourgues, and placed it in the hands of Dr. E. L. Shurly, of Detroit, to experiment with in the Harper Hospital. The results of his experiments have been published in the Harper Hospital Bulletin for April, 1893, and are as follows:

"The favorable reputation of cod liver oil, as well as other animal oils (such as cream, eulachon oil, etc.), as a means of treatment of phthisis pulmonalis is too old and widely known to need comment. It is equally notorious that very many phthisical patients, suffering with even a moderate degree of anorexia can not take these oils, either pure or in the form of emulsion. Therefore the medical profession has been ready to hail with delight any preparation or combination which might be presented that would enable patients suffering from phthisis pulmonalis to

receive cod liver oil without untoward effects. Whether the real value of cod liver oil and eulacohn oil rests with the extractives or the oily portion, is a question; but many have believed all along that the extractives contained iodine, etc., were the constituent of particular value. Hence, when so-called morrhual or other extracts were first put upon the market several years ago, they soon found a favorable reception, especially from those practitioners who relied so exclusively upon cod liver oil as a medicine and nutrient for wasting diseases." Dr. Shurly goes on to say that: "There is no doubt, from our experience, that the cod liver oil extracts are fully as efficacious in the majority of cases, and far superior in all cases marked by feeble or fitful digestion." Then follows a description of cases in which Dr. Shurly employed our alcoholic extract of cod liver oil containing the combined active principles extracted from the oil. This extract was given with excellent results. The Doctor then sums up the cases by saying: "It seems apparent that these preparations are of considerable value, especially in those cases of phthisis pulmonalis which exhibit marked and persistent disturbance of the stomach and small intestines. Whether their effects depend solely upon their nutritive value or upon some selective action upon the peripheral nerves or capillaries can not now be determined."

Various other experiments were conducted with this extract in combination with wine and peptonate of iron by Drs. Chittick, Manton, LeSeure and Duffield, connected with the Detroit hospitals. The limits of this paper, however, will not permit us to consider the matter at greater length. We hope, however, in a subsequent paper to give further information on this interesting subject.

In this connection it may be well to state that associated with me in this work on cod livers and cod liver oil have been Prof. C. C. Sherrard, of the Detroit Medical College, the chemist of the scientific department of Frederick Stearns & Co., and Prof. J. O. Schlotterbeck, of the University of Michigan, who has done a good deal of work for us on the subject.

PHARMACY IN MEDICAL SCHOOLS.

Read in the Section on Materia Medica and Pharmacy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

HENRY PARR HYNSON, PH.C.

BALTIMORE, MD.

I am led to present a paper upon the teaching of pharmacy in medical colleges for somewhat selfish reasons. This selfishness is not, however, that of the individual but is the kind which seems laudable in a loyal member of the pharmaceutical brotherhood. From the standpoint of the pharmacist, I believe a better knowledge of pharmacy, its truths, laws and practices would be greatly advantageous to medical men. This seems but a logical conclusion, arrived at through and by the acknowledged principle which makes the best and most thorough knowledge of a person, a thing or a theory, the only proper quality for justly and fully estimating the value of any of these. Does this not bring to a number of my honest hearers on "the other side of the house" the question, Am I in a position to do justice to this profession? Or, as I would rather have you style it, this branch of your profession, which has so thoroughly established itself in our midst during the last fifty years as evidenced by its separate colleges, its special schools

connected with our larger universities; by its current literature, which has grown from a small beginning in 1857 to very large proportions, devoted to pharmaceutical advancement and reports of scientific research and investigation; by its great mass of permanent literature; by its model text-books, all resulting in the preparation of men who practically edit your pharmacopœias and dispensaries, composing a large proportion of the actual workers in pharmacologic research, which looks so strictly toward a thoroughly scientific and rational materia medica. But while we make these seemingly boastful claims, we at once make due acknowledgment to medicine proper, our mother, if she will allow it, and freely admit we are entirely dependent upon her encouragement, her help and especially her just appreciation to give us the force, the confidence, the stimulus to push still further on, finally winning a creditable position among the special branches of your profession or, if not so much as this, establish a separate one whose ethics, practices and accomplishments will give it a fair standing among its sisters. We are contending that nothing will be so helpful to us as a stronger encouragement and better recognition by the medical profession and we are sure these will come to us in no more certain way than through a broader acquaintance with our claims. How this greater familiarity with the scientific and practical elements of pharmacy can be secured seems a matter easy of solution; simply give it a place, a regular full-fledged place in the curriculum of your now extended course of medicine. In making this suggestion or appeal, as you like, I do not overlook abuses, wrongs, inconsistencies, perversions or almost any charge that may be brought. You must not forget that the "black sheep" are the conspicuous members of the flock, they are black spots, and again, it is only he who is without sin who can cast the stone. No class of men know better than yourselves the effect of good strong healthy growth brought about by changed environment. How it will push aside, absorb or eliminate irregularities and malformations, which found life and place where surroundings were bad and food poor. This much we would gain by a thorough teaching of pharmacy in medical schools—strength, encouragement, a fair appreciation, a more certain and healthier growth from improved environments.

Now, what would be *your* gain? Could I get into words the advantage a physician who has a thorough knowledge feels he has in this particular line over his brother who can make no such claim, I would need write no more. Pharmacy must of necessity be practical to be valuable. Its practices are largely made up of the intelligent and skillful application of many of the facts and theories of established sciences. It is truly said, it is not so much the accumulation of knowledge as its application that makes a man great, a truth, indeed, regarding pharmaceutical attainments, which compass a broad scientific training and includes much we find in mineralogy, botany, zoölogy, together with a number of branches already included in the studies of the medical student, particularly practical chemistry, comprehensive materia medica, applied physics, some anatomy, physiology and microscopy. The study of pharmacy will help the medical student by bringing about a direct application of his knowledge through the varying reactions and combinations which occur during pharmaceutical manipulations. Surely it gives him a

more thorough knowledge of *materia medica*, since it comprehends the source, collection, preservation and preparation of drugs. It helps him in therapeutics, since he must become familiar with the exact composition of compounds, and by a more accurate understanding of the peculiar characteristics of medicinal substances generally. With this knowledge and by it he may arrive at conclusions regarding the peculiar effect of drugs, which would be perfectly impossible without it. For instance, the marked difference between the action of potassium or sodium oxalate as compared with iron or cerium oxalate. Quite clear to one knowing the pharmaceutical characteristics of these salts, and yet the application of these truths and principles gained through following other avenues is not all one finds in pharmacy. To be a good chemist, an enthusiastic botanist or one thoroughly familiar with the ordinary *materia medica* does not by any means constitute an efficient and competent pharmacist. Nor does it offer a medical man a sufficient acquaintance with this branch, although often the usual requirements of a physician are too frequently supposed by himself and his patients to better fit him for the preparation of medicine, than is the capable graduate of pharmacy. There are so very many important actions, effects and results occur which are due entirely to physical peculiarities and can be controlled only through pharmaceutical management. Where, except through a course of pharmacy, can the medical student learn of these possibilities? Notwithstanding the tendencies of the times, regarding drugs, lead almost to their entire disuse, which is simply that stroke far to the other side, and which, it seems, must be made before a proper settling is ever reached; notwithstanding this want of faith, there are times left when a physician must needs do something looking to the relief of his patient other than to regulate his diet, improve his surroundings, reduce his temperature by ice-water, cure his stomach ache by removing his appendix or overcome hysteria by ovariectomy. These simple (?) remedies are not sufficient at times to meet requirements or to satisfy the patient's demands for corrective treatment. If, indeed, drugs have yet to be used, does it not follow, to be consistent with the advances made in other direct lines, that they should be intelligently handled? Is there not more empiricism in the use of medicine than in any other branch of the profession? If empirical practice have lessened and are vanishing, have they not disappeared before the light of a better and surer knowledge? And before this same certain light will the mist so long clouding the use of medicines disappear. He, among you, who would even in this day of skepticism deny that there are a few real specifics would be most surely regarded as, at least, eccentric. If there is worth in a few agents discovered by a thorough and certain investigation of their action and characteristics, is it not possible that more of them may be established, provided they are skillfully prepared, of definite strength and always uniform in potency? I have been trying to show that a practical knowledge of pharmacy is necessary for the physician who poses as an advanced member of the profession. No one can doubt how valuable it is to those who are fond of remedies. It would be tedious to go into details of the help they would have at hand through this source. The tendencies of the times are favorable to the adoption of a pharmaceutical

course in medical schools. To ascertain to what extent the branch is now taught I addressed a note of inquiry to the proper officers of twenty-five of our principal medical colleges inclosing an addressed card for reply. Only nine of these came back, and I conclude from the silence of the other sixteen that they were ashamed that no advances have been made in this line. Adding to this nine our Baltimore's own colleges, five, we have fourteen from which to draw conclusions. Of these, five teach pharmacy separately or in connection with *materia medica*; three in connection with schools of pharmacy; six do not claim to teach it at all. One alone examines and makes a satisfactory stand a requisite for examination, and as I have the honor of being connected with this institution I can bear testimony to the great interest taken by the students and the willingness with which they undertake the study owing to the extended advantages gained thereby. These facts seem encouraging; certainly they are when we remember that the idea is almost new. Concluding, we sum up, believing to have shown: 1, that pharmacy would be greatly helped and improved if better understood by medical men; 2, that medical students would derive signal and peculiar advantages from a thorough study of pharmacy, followed by an examination; 3, that both advanced and conservative medical men would find in pharmacy means to better attain their ends; and finally, that general medicine would gain largely through the teaching of pharmacy to students of medicine, since it must of necessity bring about an improved, more dignified and ethical *materia medica*. As it is now, if I can be pardoned for the assertion, many medical men are simply made dupes of by enterprising manufacturers and their representatives. They are constantly made to believe there is a real difference between tweedle-dee and tweedle-dum. Wonderful variations are shown and accepted, between the action of one firm or another's preparation of some substance which is as fixed and as certain in its effects as anything can possibly be.

The physician thoroughly taught in pharmacy is never the material that the promoter of new and mysterious pharmaceutical products seeks or one with whom he is successful in inducing to use his really claimless compound. Doing away with this endless nameless class of remedies, which in almost every instance after a time play the part of the old-time patient, would be of incalculable benefit to medicine proper. Abolish the use of these proprietary products and unscientific compounds and the last vestiges of empiricism will go with them.

ADENOMA SEBACEUM.

Read in the Section on Dermatology and Syphilography, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY W. E. MAXWELL, M.D.

PORTLAND, OREGON.

Mr. C., age 31, single; traveling salesman; American parentage; healthy, well developed and of fair intelligence; habits not strictly temperate; raised in moderate circumstances; no epilepsy or other nervous troubles known in his family.

Beginning about half an inch below the right ear and posteriorly, running obliquely downward and backward across the sterno-mastoid muscle, is a

double parallel row of closely connected but distinct, averaging pin-head-size papules, on a slightly elevated red base, measuring one inch long by one-fourth inch wide, but somewhat narrower in its middle from arrested development and slightly bent upon itself as if broken, but not disconnected. This patch presents an irregular, rough surface of twenty-seven distinct but closely connected papules, each surrounding the dilated orifice of a sebaceous follicle, from which a slender, thread-like sebum can be expressed.

The summit of each papule is paler than the base on which it rests. The base itself is a shade redder than the surrounding surface, which is a light crimson and finely punctated, being made up of innumerable small dilated vessels. Below this patch and at its lower end and separated only by a narrow strip of normal skin, is a group of five papules similar in every respect to the patch above, but less distinct. Both patches are devoid of hair growth. No comedones near, although the papules would suggest a cluster of comedones if not for the circumscribed elevated red base.

This growth was not noticed at birth, but was in early infancy, and is said to grow redder at times. The papules have not decreased or altered in character in any way since first noticed, and he is not positive as to any increase either in number or size of papules.

Presenting himself for treatment Feb. 14, 1894, electrolysis was tried as described by Crocker in his work on skin diseases. The needle was attached to the negative pole of a galvanic battery and inserted well down into the orifice of each papule and in the larger ones making two or more insertions. Three to four milliamperes of a McIntosh galvanic battery were used. This was tried three or four times at irregular intervals, the last being August 1 following.

In December following, seeing no results from the electrical treatment and the striking similarity in the arrangement and external character of the papules in this case to the case so thoroughly studied and reported in the *Journal of Cutaneous and Genito-Urinary Diseases*, December, 1893, by Dr. Politzer, in which he obtained such satisfactory results by scarification, commended this treatment to me. My patient's limited time, however, from business relations, justified a more active procedure on my part.

The upper patch was now curetted to a point just below the level of the normal skin surface. The tissues showing quite a fibrous resistance and slightly more vascular than normal. It soon healed with a smooth pink cicatrix.

In March, 1895, he returned to my office to consult me as to an unlooked-for behavior in the cicatrix, which was likely to become more unsightly than the original growth. It had assumed somewhat the appearance of a hypertrophied scar. He was told that it was probably (?) a beginning cyst formation and advised to report later. On his return in April a very slight increase in size could be observed. It was punctured in several places, but nothing more than blood escaped. It had not felt sore nor painful at any time. The lower patch was not curetted and remains as first seen. Under his right eye was a varix about the size of a pea, which has been obliterated by electrolysis. A few telangiectic vessels of small size can be seen on left side of his face and one above left eye. He says tumors have been known in his family, but the nature of which he could not

tell. No microscopic examination has been made. The diagnosis given is on clinical grounds.

Whether a return to the original condition to which it at present bears no likeness, or hypertrophied scar or keloid will be the result of treatment, I will know later. Except the occurrence of cystic and colloidal degeneration in the growth, I find no report of the return of any other than the original growth from incomplete removal.

The clinical behavior in this case bears some points in common to cases reported by Crocker of congenital fibro-sebaceous disease, more especially the one referred to him by Bilton Pollard in 1890:

1. In its probable congenital origin.
 2. Its changeable color at times.
 3. Its slightly elevated base.
 4. Being devoid of hair where hairs normally exist.
- It differs from Pollard's case, however:
1. In the larger size papules; the follicular openings in the papules with the sebaceous contents.
 2. The absence of comedones.
 3. The presence of telangiectases near and remote.

Of the few unilateral cases reported, this is the only one away from the face and on the neck. It is the first American and second case reported in America, and is reported for its rarity, its unilateral and unusual location and yet unsettled termination.

I now propose to make a section of it when its further pathology will be studied. Its location and definite arrangement, even for cosmetic effects, would have justified it at first.

Later: The new growth is keloidal.

SYPHILITIC ULCERATION OF THE RECTUM.

Read in the Section on Dermatology and Syphilography at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY JAMES P. TUTTLE, M.D.

ADJUNCT PROFESSOR OF SURGERY AND LECTURER ON DISEASES OF THE RECTUM AND ANUS IN THE NEW YORK POLYCLINIC.

While syphilis is acknowledged to be the most frequent cause of stricture of the rectum, and the profession at large are well posted as to this fact, I have been surprised in post-graduate teaching to find how little the *modus operandi* of its production is understood, and how little the prodromic and precursive conditions are appreciated.

I do not propose in the present paper to discuss stricture of the rectum in a general way, as this would lead me into too wide a field. In order, therefore, to make plain the bearing of my remarks it may be well to state at the outset that I have little faith in any syphilitic stricture of the rectum, that has not been preceded by ulceration of that organ. Gummata may produce narrowing of the canal as in the cases reported by Zapala (*Arch. f. dermat. und syph.*, Prague) and Molliere, but certainly it is very rare. The condition described by Fournier as ano-rectal syphiloma is said to have been seen by numerous observers, but there is no positive proof that ulceration had not preceded the infiltration, which is its chief characteristic. If the doctrines of Fournier on ano-rectal syphiloma, and Trelat on quaternary muscular infiltration and atrophy are correct, there is no anatomic or physiologic reason why we should not have similar strictures all along the alimentary canal just as frequently as at the rectum, which we all know we do not have. Ulceration is in my opinion, then, the almost invariable precursor if not the cause

of syphilitic stricture of the rectum and is, therefore, the important element to be understood; the essential condition to be diagnosed.

When once the muscular wall has become infiltrated, its fibers atrophied and the interstitial tissue becomes sclerotic, there is no longer any hope of curing the stricture. Our only course then is palliation or resection. When the condition is recognized in its early ulcerative stage, before the above lesions have taken place, much may be done; indeed, the large majority of the patients may be cured. With this exalted view of its importance, I thought it not unfit to bring before this society a brief discussion of the clinical characteristics and course of syphilitic ulcerations of the rectum.

We may hastily run over, without discussing, the syphilitic manifestations about the anus, such as chancres, condylomata, erythema, secondary skin lesions, deep ulcerations, the result of friction and uncleanliness of the parts, fissure-like cracks, dry, brittle mucous membrane, mucous patches, etc. These manifestations occur early in the course of syphilis, indeed, they are generally associated with the secondary skin eruptions. Where they have a tendency to advance rapidly, and to great destruction of tissue, they are generally associated with some profound constitutional disturbance, such as nephritis, cirrhosis of the liver, or tubercular diathesis. These conditions should be borne in mind and inquired into with the utmost precautions. These secondary manifestations about the anus are important in themselves, but not pertinent to the point we have in mind. They are not likely to be overlooked and their nature is generally apparent. They are, consequently, treated early and cured before much damage has been done. These facts will explain in a large degree why we so rarely have syphilitic stricture of the anus. It is within the external sphincter that we find the dangerous ravages of specific ulceration. Van Buren said years ago, "When we consider how rarely the rectum is carefully explored, except when painful symptoms render this measure necessary, and that secondary eruptions are usually painless, the absence of recorded cases of secondary ulceration is not difficult to understand; while the common occurrence of secondary syphilitic manifestations at the other end of the alimentary canal—in the mouth and throat—justifies the assumption that they also occur if not so frequently, in the rectum."

We are examining more rectums now-a-days and find that the predictions of this eminent teacher are more than justified. I shall not depart from the ordinary divisions of primary, secondary and tertiary lesions. The initial lesion is rarely seen in the rectum; first, because, as I believe, it is very infrequent, at least in this country, and second, because it produces so little disturbance if within the mucocutaneous border, that it heals before the patient has occasion to consult a physician.

The primary sore in the rectum differs in no wise from that seen elsewhere, except at the verge of the anus between the mucous folds, when it may assume the form of fissure in ano. Care should therefore be exercised in examining all cases of fissure, to see that there is no localized induration at the point of ulceration; that its borders are not elevated, and that there are no other concurrent symptoms of syphilis in the individual. Especially is this important

in women as the rectum in them is so exposed to contact with the male organ. The existence of pain in these fissure-like ulcers is no proof that they are not syphilitic, for if they involve the mucocutaneous border they are almost as painful as any other form of fissure.

The primary lesion in the rectum has been so rarely recognized that many eminent syphilographers have denied its existence *in toto*. Those who have read the reports of Fournier, Martineau and Hartley certainly can not doubt its existence, and I do not care to enter into any further statistics to prove it. They may occur as abrasions, erosions, round, crater-like ulcers, brown papules, or, as said before, as fissures between the mucous folds. All these manifestations are distinguished from similar non-specific lesions by a history of exposure, and by their localized cellular induration and infiltration. They do not involve the deeper layers of the gut; they heal in about three weeks or less, leaving a slight induration, rarely a cicatrix and no stricture. They will be rarely seen and more rarely diagnosed, but as we do not any longer treat syphilis at its initial stage unless some constitutional manifestation is apparent, little harm will be done by our failure to recognize these early signs.

Between the secondary and tertiary syphilitic ulcerations of the rectum, it is almost impossible to draw the line, unless we make it in weeks or months. Ulcers of secondary appearance may come on years after infection, just as a secondary skin eruption may recur after five or ten years in a properly treated case of syphilis. I prefer, therefore, to confine the term tertiary to ulcerating gummata and call all others secondary or secundo-tertiary. The time at which these ulcers occur varies from the third week after infection to the most remote period of life and their characteristics do not differ much whether occurring early or late, with the exception that the later in the disease the more likely are the ulcers to involve the deeper layers of the rectal wall. They are of variable shape, generally oval, but running up and down the rectum instead of around the gut as is the case in tubercular ulcers. They are crenated, crater-shaped, with sharply cut, infiltrated edges, never undermined, with grayish, sluggish-looking bases and bleed easily upon touch or friction. This condition of the edges, this color of the bases, this hemorrhagic tendency, positively diagnose these ulcers from tubercular ulcers which have a light yellowish look, are nearly always undermined, and ragged at the edges, discharge a thick muco-pus and rarely bleed. The early secondary syphilitic ulcers do not as a rule involve the muscular layers of the rectal wall, but if superficial and if treated at this stage they disappear, leaving behind no cicatrix or contraction. They soon become chronic, however, and invade the deeper tissues, one after the other, until they lay bare the sacrum, perforate the vaginal wall, or even the peritoneum itself. The ulcers have a tendency to extend up the bowel, instead of around it, although they do sometimes take the latter course, and as they advance from point to point the older portions heal and leave behind a smooth, white, depressed cicatrix, with slightly pigmented borders, the essential characteristic of which is to persistently contract. The bases of these ulcers are at first soft and edematous, but as they become more chronic and progress, cellular infiltration takes place in the submucous and mus-

cular coats. The walls of the rectum assume a stiff and leathery feeling, and narrowing of the canal begins. The muscular fibers degenerate into fibrous tissue and there is left a contracting, connective or cicatricial tissue, the prominent feature of which is to hypertrophy and contract, and this is the condition which produces incurable stricture of the rectum. During this formative stage, we may have almost an occlusion of the gut, by a tissue differing much from the dense and cicatricial tissue which is the last stage of syphilitic stricture. In this condition there is a localized, cellular infiltration, which is not dense and hard, but soft and easily torn and composed of new, embryonic cells as will be seen from the following pathologic examination given by Mallassez (*Dict. Encyc.* page 728). "At the level of the contracted portion, at the point most elevated and least permeable, which offers to the introduction of the finger and the passage of matter a great resistance, were found, not as is ordinarily taught, a tissue analogous to cicatricial, but a tissue analogous to 'bourgeons charnus'—proud flesh. This tissue, formed of new elements, is very vascular and offered little resistance to instruments when one sought to dilate it; it was only lower down in the widest part of the stricture that there were seen fascicles of hard, connective tissue surrounded by embryonic tissue and presenting the characteristics of cicatricial tissue. Between the fascicles of the muscular tissue were found also a large number of embryonic infiltrated elements, which reunited themselves at certain points.

... Finally, in the part which was below the stricture and which corresponds to the sphincterian regions, one observed almost always the cicatrices of the old ulcerations." From which it appears that the hard connective or cicatricial tissue stricture is the result of preceding ulcerative processes.

In women, recto-vaginal fistulae are more likely to be found before the permanent cicatricial stricture is formed, and in my experience they are invariably below the contracted point. Especially is this the case if there be anterior rectocele, because the hardened masses of feces and the irritating discharges lodging in this pocket, the walls of which are already thin and inflamed, cause sloughing and breaking through into the genital tract. These fistulae are not due to straining in order to pass the contents of the bowel through a strictured channel, but are purely the result of ulcerative processes. Curling (*Diseases of the Rectum*, page 112) and Paget (*Medical Times and Gazette*, 1865, page 279), seem to take the view that these ulcers are extensions from condylomatous developments about the anus. I have never seen a case which would confirm this view. Indeed I believe that condylomata are secondary to the ulcerations, and due to the irritating discharges from them, together with lack of cleanliness about the parts. The ulcers nearly always begin above the external sphincter, and there is a border of healthy, mucous membrane between them and the cutaneous border. They may be multiple, and extend throughout the entire extent of the large intestine but as a rule they decrease in size and frequency as we ascend the colon.

The first stages of stricture consist of ulceration, followed by a cellular deposit of soft embryonic tissue in the sub-mucous and muscular walls of the gut. This tissue becomes organized into connective tissue, hardens, contracts, and the surfaces heal over leaving a shining, bluish-white cicatricial appearance.

In their early stages these strictures are soft and dilatable, but after the cicatrization has taken place the muscular tissues become infiltrated and atrophied or degenerated, and dilatation is no longer practicable. The early recognition of the ulceration, and the prevention of these later sequences should therefore be the aim of syphilographers and rectal surgeons. When the permanent stricture has once formed, the condition is more in the domain of the general surgeon than of the syphilographer. Prevention of stricture is our province—not its cure.

Prevention may be accomplished to some extent, in the following ways: 1, by systematic subjective and objective examination of every syphilitic patient with regard to the involvement of his or her rectum. The patient should be warned what to look for and at what period he should expect these manifestations. The use of the speculum, where the finger is not educated or where one feels any suspicious condition is of the utmost value. 2, by examining every case with rectal ulceration with reference to specific taint. Within the past year I have had sent to me as cases of cancer, three undoubted cases of syphilis of the rectum. Two of them, fortunately, had not reached the cicatricial stage of stricture and are now comparatively well. 3, we should be careful and accurate in our diagnosis between simple traumatic, tubercular and syphilitic ulcerations of the rectum. The history of the case may, or may not be of value. Many cases of syphilitic ulceration of the rectum are cases of "syphilis innocentium" and unwittingly deceive us in our subjective examinations.

The presence of pain is no proof that an ulcer is not syphilitic. It is the location of the ulcer of the rectum which governs the pain rather than its nature. A syphilitic ulceration upon the muco-cutaneous border is just as painful as any form of ulcer, and a traumatic ulceration of the rectum above the external sphincter is just as free from pain as a syphilitic ulcer. The history of constipation, the use of enemata or other instrumental or digital manipulation of the rectum would suggest a traumatic nature for the ulceration. Yet these conditions existing and producing the ulcer, if there be constitutional syphilitic taint, the ulcer, originally simple, may take on a syphilitic nature and progress as other syphilitic ulcerations. Ulceration of the rectum from cirrhosis of the liver or kidneys is of a shallow character, associated with profound constitutional disturbances, it involves the mucous membrane, generally, of the entire rectal cavity, and occurs in the later stages of these diseases. It is not likely to be confounded with specific ulcerations. Chronic, advancing ulceration of the rectum, with cicatrizing border at its earlier points, is almost invariably syphilitic. Dry, brittle, mucous membrane about the anus, which cracks open by slight distention or upon the introduction of the finger, or pale pink, crenated, hypertrophied folds of the lower border of the mucous membrane are very likely to be associated with constitutional syphilis and frequently with ulceration higher up.

Nevertheless, these conditions are not positive proof, as the French and some English surgeons claim, of syphilis. The ulcers of the rectum which are likely to be confounded are the tubercular and syphilitic. The distinguishing points between these two varieties may be stated as follows:

Tubercular Ulcer.—Hereditary predisposition; general constitutional appearance; other organs may or may not be involved; base yellow; edges undermined, not indurated; ulcers if multiple, do not generally coalesce but are united by submucous fistulae; do not advance upon the surface, but burrow and form pus cavities and fistulae; pus thick, stringy, scanty; rarely bleed; the deeper tissues seldom involved; no tendency to heal as they advance from point to point; no infiltration or atrophy of muscular wall; little if any tendency to contract or produce stricture.

The crucial test is the finding of tubercle bacillus; but failure to find it is only negative evidence and of little value.

The therapeutic test is of little value in the diagnosis of rectal ulceration as the most thorough anti-syphilitic treatment will generally fail to cure an ulceration of the rectum unless associated with proper local measures. There is one form of local tubercular ulceration which is very difficult to distinguish from ulcerating gummata. These both begin in globular, elastic, sub-mucous swellings. In their early stages they are not attached to either the mucous membrane or muscular wall of the gut. They may be single or multiple; of small or large proportions. The gummata are harder, less elastic and more likely to be multiple than the localized tubercular manifestations. They are also generally associated with other tertiary syphilitic lesions elsewhere in the body. Mollière says they do not suppurate but undergo a sort of fatty or cheesy degeneration and thus break down. The localized tubercular ulcer discharges pus, its edges are undermined and there is only a slight inflammatory zone about them. They are acute and yield readily to local treatment. The gummatous ulcer, on the contrary, discharges little pus, it is chronic, is surrounded by an inflammatory zone and does not yield to local treatment unless associated with constitutional therapeutics. It remains chronic, eventually involves the deeper walls of the gut, and may be the commencing point of syphilitic stricture of the rectum, but the ulceration remains still the essential factor in the production of the fibrous, cicatricial condition.

TREATMENT.

The constitutional treatment of these conditions does not differ from that of syphilis elsewhere. Mercury, however, should not be given internally in these conditions as it is necessary to give the parts as much physiologic rest as possible. It should be used by hypodermic injections, inunctions or sublimations. The iodids should be administered in the form the least irritable to the stomach. I have recently given it in a solution of pepsin and this solution administered in milk. Another plan which has been suggested to me by Dr. Dillon Brown of New York, consists in dissolving the iodid in milk, and making of this a rennet whey, the fluid part of which retains the iodid and this is administered to the patient. It is a most unirritating solution and seems to agree with the most delicate stomachs.

For local treatment, except in the gummatous form of ulceration, I do not believe in irritating or cauter-

Syphilitic Ulcer. Hereditary or acquired history; ulcers generally single; bases gray; edges indurated, sharp cut and not undermined; if multiple, ulcers unite by coalescence; pus very serous and always bloody; deeper tissues always involved when ulcer has existed for any length of time; progress rapidly, and generally up the gut, instead of circularly; tendency to heal as they advance and leave contracting cicatrices; muscular and submucous walls of gut infiltrated, stiff and leathery; constant tendency to contract.

izing agents. Soothing and protective remedies have yielded the best results in my hands. Irrigation with boric acid or pyoktanin solutions, the application of slightly stimulating remedies, such as weak solutions of nitrate of silver, sulphate of copper, carbolic acid or bichlorid of mercury, and the insufflation of iodoform, or better still, aristol, upon the ulcerated points will generally cause them to heal and relieve the uncomfortable sensations of the patient. Recently I have obtained a very rapid healing in one case from the local application of a 10 per cent. solution of alumnol. Where this course of procedure does not result in cure we have one recourse, and that is absolute physiologic rest to the parts. This is given by inguinal colotomy; the formation of an artificial anus through which all the fecal matter shall pass and the continuation of our local treatment. If the ulceration heals following this procedure, and does not leave a dense, fibrous condition of the rectal wall, the artificial anus may be closed and the passage of the feces restored to their normal channel. If there is a dense, cicatricial condition of the rectum left, then it would be wiser either to close the rectum permanently and let the patient bear the artificial anus through life, or to resect the strictured portion of the rectum and bring the healthy portion of the gut down and attach it to the anus or that portion of the rectum which is not involved, above this orifice. In the localized gummatous form of rectal ulcers, scraping out of the diseased tissue with a sharp spoon and then treating it as a simple ulcer, together with constitutional anti-syphilitic treatment will generally result in a cure. These methods applied with the early recognition of the disease will save us the mortification of seeing so many incurable strictures of the rectum and will avert a world of suffering to those who seek our aid, but beyond and above all methods of treatment is the importance of early recognition in these cases.

PSEUDO-CHANCRE.

Read in the Section on Dermatology and Syphilography, at the Forty-sixth Annual Meeting of the American Medical Association, held at Baltimore, Md., May 7-10, 1895.

BY WILLIAM S. GOTTHEIL, M.D.

DERMATOLOGIST TO THE LEBANON HOSPITAL, THE NORTHWESTERN AND THE GERMAN WEST-SIDE DISPENSARIES.
NEW YORK CITY.

Few syphilographers doubt the existence of syphilitic reinfection, but most of them regard it as an occurrence of extreme rarity. The literature teems with recorded cases; but an exact analysis shows that the vast majority of them is open to grave doubt. They are either cases of manifestly incorrect diagnosis, or they are cases so imperfectly recorded that they lose all value as evidence in this much disputed subject.

Until the middle of this century the law of Ricord obtained universal acceptance. Syphilitic immunity, once established, was supposed to last during the remaining life of the patient. And the exceptions that were noted were so infrequent and so insufficiently proven that they detracted nothing from the validity of the general proposition. Petit, Fournier, and the entire Parisian school accepted it absolutely.

In the year 1858, however, renewed attention to these exceptions was called by Zeisse.¹ He showed conclusively that in certain cases re-infection did oc-

¹ Lehrbuch der Syphilis, 2d ed., 1872, p. 58.

cur, and that absolute immunity after one attack was not the invariable rule in syphilis any more than it was in the infective diseases of acuter course and similar nature, such as variola, morbilli, etc. He was soon followed by others who collected series of cases of alleged re-infection. Gascoyne² had twelve cases; Caspary³ three, and Diday⁴ twenty-five. In more recent times Scarenzio,⁵ Morel Lavalee,⁶ E. Feibes,⁷ Glasgow Patteson,⁸ Salsotto,⁹ Koebner,¹⁰ Pauly,¹¹ Pospelow,¹² Diday and Doyen,¹³ Eichorst,¹⁴ Lang,¹⁵ Peters,¹⁶ Swinburne,¹⁷ Fisichella,¹⁸ have all reported similar cases.

When we examine these cases critically we notice especially the paucity and incompleteness of the history of the so-called second attack of the disease. As a rule the sclerosis is the only symptom that is noted; the other manifestations of secondary disease being so mild and uncharacteristic, when present at all, that we may well be left in doubt as to the true nature of the so-called chancre.

Sigmund long ago pointed out¹⁹ that there occurred tertiary ulcerations that possessed all the characteristics of the true sclerosis; and Fournier²⁰ classified several lesions which simulate the initial chancre. Brègeal²¹ called attention to gumma of the penis; the frequency of its occurrence rendering it extremely liable to be mistaken for a primary lesion. Von During²² has observed pseudo-chancres in which an apparently characteristic induration lasted for from five to six weeks, and which were never followed by secondary symptoms. Keyes²³ believes that in most of the recorded cases of a second attack of syphilis a pseudo-chancre was mistaken for a true sclerosis, and Taylor, at a recent meeting of the New York Dermatological Society, expressed a similar opinion.

Finally, the doubt as to the real existence of a re-infectio syphilitica has gone so far that Hudelo,²⁴ making an examination of 148 recorded cases, hardly admits the validity of nine of them. Nevertheless, there are a few undoubted cases. Some of those recorded by the authors mentioned above seem to be beyond suspicion, and Hutchinson's case, which occurred in a physician, can not be doubted—more especially as the patient had had variola twice.

The following lesions may simulate a true chancre:

1. *An Artificial Induration.*—Such as may be produced on a herpetic or chancroidal ulceration by the use of nitrate of silver, carbolic, nitric or acetic acids, the acid nitrate of mercury, or even alcohol. This is undoubtedly a frequent source of error, and it requires the strongest corroborative evidence in the shape of other early syphilitic lesions to diagnose as a chancre any ulceration that has been treated in such a way

2. *A Nodular Lymphangitis in Gonorrhea.*—If phymosis is also present the nodule can be felt but not seen, and until the glans can be exposed again we must remain in the dark. Even if there is no phymosis the nodule may be exulcerated, and we must suspend judgment.

3. *Scabies.*—Here lesions on the penis are the rule, and form one of the diagnostic points of the disease. If now such a lesion has been scratched or irritated in any way it is quite liable to be mistaken for an initial lesion.

4. *A Secondary Induration,* occurring late in the disease at the site of the initial lesion. This is the pseudo-chancre of Fournier, and whilst it is of rare occurrence, it exactly simulates the original tumor.

5. *A Papule or Tubercle* situated on the penis as part of a more or less general specific eruption. This has to a certain degree the same characters as the chancre, being a small-celled accumulation of similar morphologic characters.

6. *An Ulcerating Gumma.*—This is especially likely to deceive when situated on the corona, where induration is with difficulty determined. Of not infrequent appearance in late syphilis, its beginning as a submucous induration, and its hard base and border when ulcerated, cause it to simulate an initial lesion very exactly.

7. *An Epithelioma.*—In certain cases the exulcerated tumor with glandular involvement may render the diagnosis difficult. All of these pseudo-chancres are fertile sources of error in diagnosis. All of them may look so like a true chancre as to deceive even an expert. Some necessarily occur in patients already syphilitic; in others the patient may or may not have had the disease.

The two cases of which I present you models and a photograph to-day are cases in point. Both were regarded as initial lesions by competent judges; the first one might have been recorded as a case of true sclerosis without true subsequent systemic infection, whilst the second was apparently a case of true re-infectio syphilitica.

Case 1. Rudolph H., German, 44 years old, of robust physique and healthy color, came to me at the beginning of September, 1893, to consult me concerning an ulceration on the frenum and the under surface of the sheath of his penis.

His history was as follows: He was a married man with a perfectly healthy wife, and he had not been delving in extramarital fields. This usually valueless statement acquired some little importance when I got to know him intimately, as I did later on, and to appreciate the happiness of his home life and his character for veracity. He was quite at a loss to account for his sore, unless it had been acquired in a manner which I personally believe does sometimes occur, in spite of the ridicule that is heaped upon it. The son of the man in whose office he was employed was suffering from an enormous sclerosis of the under surface of the glans, which subsequently became phagadenic; he was under my care at the time, and developed later on so bad a general papulo-squamous syphiloderma that I sent him to Aix-la-Chapelle to get him out of the way of his friends. This boy was in the habit of dressing his sore whilst sitting on the only water-closet belonging to the office, and spending a considerable portion of the day at that agreeable occupation. All the employés of the office knew exactly what was the matter with him, and they were loud in their complaints at the dangers they supposed they were compelled to run. H. did not contend that this was the source of his infection, but he knew no other way to account for it and his sore was exactly on the spot where one would expect it to be had an accidental inoculation occurred in the manner indicated.

He first noted a little lump in the frenum at about the end of July; it gave him no trouble at first, but grew rather rapidly and soon began to ulcerate. The physician whom he consulted diagnosed a syphilitic chancre and treated it with vasoline for a week. It grew steadily worse, however, spreading in size and

increasing in hardness; the ulceration became deeper and the discharge more profuse. Bubo was not present, nor was there any pain. His physician then changed his diagnosis to that of chancroid and used the nitrate of silver stick, followed by powdered boric acid. This cauterization was repeated twice in the next four or five weeks, but the sore continually increased in size. The patient then consulted a specialist in a neighboring city, who also declared the ulceration non-specific, and touched it up with nitric acid, dressing it afterwards with aristol. Nevertheless there was no improvement; the ulceration progressed.

□ On Sept. 11, 1893, I saw him for the first time. The penis was edematous to a considerable degree and situated at the frenum and on the sheath just below it was a large irregular ulceration. It was oval in shape, with its long diameter transverse to the shaft of the penis: it was fully one and a half inches broad and one inch in length. The cast that I show you was made some time later, when the healing process was already well advanced: it is less in size than when I first saw it, but it shows the characters of the ulceration with fidelity. From the main lesion a thin line of ulceration extended up along the frenum onto the under surface of the glans: and here was situated a second smaller ulceration similar in character to that below.

□ The base of the ulcer was clean and fairly well covered with granulations. The margins were sloping and not undermined. Most characteristic, however, and most striking, was the induration. It was very marked, brawny to the touch and sharply circumscribed from the surrounding tissue. On the glans it was, of course, not so marked, but still perfectly evident. The entire mass was apparently a well defined tumor with superficial exulceration. It was a typical sclerosis, as far as the physical signs went.

Fig. 1.—Pseudo-chancere: herpetic or chancroidal ulceration with artificial induration. Cured by calomel locally; no internal treatment; no signs of syphilis.

The only other sign was a bilateral adenopathy. The inguinal glands in both groins were tumefied, hard and painless. Though not as stony as we frequently see them in the infecting chancere; they were not the painful, enlarged buboes of chancroid.

Other symptoms there were absolutely none—neither general adenopathy, rheumatism, defluvium capillorum or exanthem. The ulceration had been present for seven weeks.

I was naturally inclined to diagnose chancere, though I felt by no means certain that that was the case. I applied an iodoform dressing and awaited results. I kept the patient under careful observation, seeing him almost daily.

In one week's time it was very evident that the iodoform was doing the patient no good; the ulceration was extending. Calomel was then used, and with a marvelously satisfactory result. Improvement commenced at once, and though slow, was unbroken. The ulceration steadily healed, but the induration remained unaffected. By November 1, cicatrization was complete, but a marked and apparently characteristic induration, larger than a large bean still remained. This was still present, though smaller, on Jan. 1, 1894.

Meantime I watched the patient very closely for

the slightest appearance of anything that would indicate systemic infection, but without finding it. The examinations were frequent and not perfunctory. The entire integument and all the cavities of the body were closely scrutinized. At the present writing, nearly two years after the first appearance of the sore, I am able to say that there has never been the slightest symptom of secondary syphilis.

Unless we are willing to admit that a chancere accompanied by inguinal adenopathy may be the only result of infection with the specific virus, we must regard the lesion in R. H.'s case as a false or pseudo-chancere belonging to the first class of artificial indurations. And this in spite of the very clear history of its beginning as a subcutaneous nodule given by the very intelligent patient, and in spite of the hardness, painlessness, absence of chancroidal bubo and cure by calomel powderings. Whether it was originally a herpes or a chancroid it is impossible to say, but it falls within the category of those cases that I have ventured to call pseudo-chanceres.

Fig. 2.—Pseudo-chancere. Indurated exulcerated lesion simulating chancere. Complete history of syphilis three years before. Ulceration one month old; spreading. No other evidences of recent syphilis. Rapid cure under KI internally. G. W. S. D., March, 1895.

Case 2.—F. M., 41 years old, a tall and thin but otherwise fairly healthy looking man, consulted me on March 20 of this year for an ulceration on the under surface of his penis. Though only a mechanic, he is a fairly well-educated German, and he gives a very clear and precise history of his case as follows: Three years ago he had a chancere which was soft at first, but subsequently became quite hard. It appeared exactly four weeks after intercourse, and the scar that it left on the glans penis is still visible. It was a lump as big as a bean or larger, and was treated by the physician to whom he went with gray ointment. After a time it ulcerated, but the hardness lasted fully two months after the ulceration had healed. A few weeks after the appearance of the tumor an eruption of pimples appeared all over his body, for which the doctor gave him drops. He had also persistent headaches, a bad sore throat and falling of the hair. In fact, he gives a circumstantial and complete account of syphilitic infection at the date mentioned. Since that time he has had occasional eruptions of pimples on the body, but he got tired of taking medicine and has had none at

all for two years past. The spots always went away of themselves in time.

He complains now of a sore that appeared on his penis some four weeks ago and which he calls a chancre. Examination shows the presence of a kidney-shaped ulceration situated on the under surface of the penile sheath near the preputial orifice. Its concavity is toward the meatus, and it measures one and three-quarters by one inch. Its margins are extremely distinct, raised and rounded; its edges are sloping; its base is covered with granulations intermixed with a small amount of necrotic tissue. The tissue immediately around and under the ulcer is distinctly indurated, and whilst not very hard, it is sharply limited, and can be readily differentiated from the soft tissue of the sheath. The ulcer has been gradually increasing in size since it began, but there has been no pain nor has it inconvenienced him in any way. There has been no treatment.

Examination of the patient's body revealed the following facts: There is a slight inguinal and cervical adenopathy, otherwise the glandular system seems normal. On the glans penis is a distinct scar, which the patient says is the mark left by the initial lesion of three years ago. At three or four places on the trunk and limbs are groups of characteristic large papular lesions which tend to spread peripherally. They have been present for several weeks, and the largest and oldest are covered with a crust, the removal of which reveals central breaking down. On the anterior surface of the left wrist is a distinct gumma, one inch in diameter. It was opened some five weeks ago by a surgeon under the impression that it was an abscess. Besides this there are on various places over the body groups of small circular cicatrices. Some, the more recent, are still pigmented, others are white and atrophic.

Treatment revealed the correctness of the diagnosis: recovery complete and rapid under iodid of potassium.

The patient then has a florid syphilis in its tertiary stage, as is evident by the unsymmetrical papular eruption and the gummata. He has a gumma of the penis, which presents enough of the characters of an initial lesion to be mistaken for one, especially on a hasty or superficial examination. He had what I may venture to call a typical pseudo-chancre, inasmuch as it looks and feels like one.

There is, so far as I am aware, no characteristic and no combination of signs that will enable us to diagnose a chancre. Only the advent of other symptoms in their proper order gives us data to form an opinion as to the existence of systemic infection or not. And we must look with grave doubt on all reported cases of syphilis with indefinite and badly marked secondary symptoms, such as almost all the cases of reinfectio syphilitica are.

37 West Fiftieth Street, New York City.

SOME REMARKS ABOUT ASEPSIS IN MILITARY SERVICE.

Read at the Meeting of the National Association of Military Surgeons, Buffalo, May, 1895.

BY LIEUT. COL. EDWARD BOECKMANN.

ASSISTANT SURGEON-GENERAL OF THE MINNESOTA NATIONAL GUARD.

(Concluded from page 172.)

Very recently something has been written about catgut, which can be boiled after treatment with formalin, a 40 per cent. solution of formol (formaldehyde), a tanning agent of pronounced antiseptic properties. Thereby nothing is accomplished. Formalin evaporates during the boiling; the catgut, which formalin has converted into a sort of absorbable wormgut, is sterilized like the last only on the surface. Those microorganisms, not destroyed during the hardening with formalin, whose germicidal power in a given time is very feeble, are liberated, as the catgut is absorbed, from the interior which is not affected by the boiling water. Consequently I do not hope much for formalized catgut which can be boiled. Tanned catgut, either formalized or chromicized, has, however, an apparent advantage in being ab-

sorbed slowly; I, for my part, do not see any reason for using any but the fat-containing, sterile catgut, which resists absorption sufficiently long. In order to preserve catgut as a skin-suture to the exclusion of all others, it will be necessary, so far as I am able to judge, to continue along the line indicated in retaining the fat and to seek an agent, which will render catgut an impossible culture medium and remain with it, until the last fiber is absorbed. Lano-linized catgut seems to be a step in advance, but the last word has not yet been said, for which reason I would provisionally recommend my catgut to you as a specially adapted all-around suturing and ligating material in military service.

Boiling water is an excellent germicide and is excelled only by the free flame, which however has but little practical application. Boiling water kills all surgical bacteria, spore-bearing or not, in the course of a minute or two. The pyogenic bacteria according to Sternberg's world-famed tables are destroyed in 10 minutes by moist heat at about 150 degrees F., which corresponds to boiling for as many seconds. Moist heat is consequently disproportionately much more powerful than dry heat; the reason why is not definitely settled. It is probably a purely mechanical boiling to pieces of the capsule of the bacteria. Boiling is such a safe, quick, easy, economical and non-injurious method of sterilization that it can not be too strongly advocated, wherever it is practicable. Boiling is and will be our favorite method for the instruments. By making the water alkaline with soda or still better with green soap its sterilizing power is increased, as the instruments are at the same time cleaned and the temperature somewhat increased; twisting is prevented and the cutting-edge of sharp instruments not markedly affected. The instruments must not be placed in the water before the latter boils, and it can not be too strongly emphasized, that they should always be kept in first-class condition at all times. I know of no practical method of preserving instruments sterile and ready for use; if they are boiled and thoroughly cleaned after each operation, it is only necessary to place them in a tray and cover them with boiling water at the next operation and they are perfectly safe after a few minutes standing.

Although the boiling of instruments can take place in any vessel whatever, it is desirable, especially on the field, to be supplied with a specially constructed instrument-boiler. Such a one is depicted below. It is constructed on the principle of the steam sterilizer, illustrated further on, and consists of three separate parts: the boiler, instrument-tray and the cover. The boiler is filled with sufficient water to cover instruments; some soda, green soap or even lysol is added. The cover, formed like a pan and fitting inside the boiler is adjusted as shown in the illustration. The apparatus is placed on the fire, while the instruments are arranged in the wire-tray. When the water boils, visible at the border of the boiler, the latter is uncovered to receive the instruments. The central tube, which in no way interferes with the instruments, prevents the water from boiling over, by conducting off the formed steam, which disappears invisibly under the bottom by passing over a hot plate, not shown in the drawing; the plate protects the flame from extinction by the steam. Five minutes boiling is all that is needed; the boiler is removed from the fire and placed on a stand convenient for the operation. The cover which has been

sterilized simultaneously, is lifted out and turned over; the instrument tray is deposited within the cover. The boiled water serves many purposes during the operation. I cherish the hope, that this compact, transportable instrument-boiler is eminently adapted for operations in the field.

Steam, water in gaseous state, follows closely boiling water in germicidal power, when it has its temperature, when it is unmixed with air (saturated), when it penetrates the articles to be sterilized and when it condenses its moisture in every single particle thereof. If these precautions be observed, the articles concerned will be literally boiled in steam, resembling what occurs in boiling with water. Steam can consequently not cleanse everything; articles to be sterilized by steam must therefore be washed beforehand, if they are not clean. Steam is more particularly adapted to porous materials; solids are disinfected by steam solely on their surfaces; fluids are not sterilized by the steam itself, but by the heat communicated by the latter. In order to sterilize water, watery solutions or emulsions, like milk for instance, it is therefore perfectly indifferent, whether the containing vessel is placed in steam, boiling water or hot air. Concerning sterilization of fatty substances it must be remembered, that they can not derive the benefit of moist heat at all, because they either do not contain water or, like lanolin, contain it in such a manner, that it becomes separated. Consequently the sterilization of fatty matters by the aid of steam means a dry heat sterilization, ineffectual because of the low temperature.

Concerning the temperature of the steam, boiling water will at the ordinary pressure of the atmosphere at the sea-level give off steam at 212 degrees F.; this is *low steam*. The higher the altitude, the less consequently the pressure and the lower the temperature of the boiling water and its steam. This should be borne in mind when sterilizing with steam or boiling water at high altitudes. Steam of higher temperature than 212 degrees F. is obtained by conducting it through heated pipes or into heated chambers—*super-heated steam*, or by evolving it under pressure, *high steam*. All pathogenic bacteria, we know, sporebearing or not, are destroyed in steam at 212 degrees F. in the course of five minutes, low steam is therefore as regards temperature surgically perfect. Super-heated steam resembles hot air in germicidal power; its temperature must consequently be raised considerably and it must be continued for hours in order to destroy spores. High steam on the contrary is more powerful than low steam. High steam at 221 degrees F. will, in the course of ten minutes, kill all kinds of spores—pathogenic or not. No spores are capable of germinating when a high steam temperature of 230 degrees F. is reached. The high steam is not only surgically, but also bacteriologically perfect. Where the temperature at high altitudes is below 212 degrees F., the sterilization must be continued beyond the above mentioned five minutes, what we usually

also do at lower lying situations, where we “for safety sake” let the steam play for half an hour or more.

Concerning the penetration of the steam, we all know by experience, how much more easily steam penetrates than hot air. It is in addition a matter of fact that steam, which streams from above downward, penetrates to perfection every single particle of the porous materials in its path, because it, on account of its lower specific gravity than air, travels in a vertical column to a horizontal plain, while steam, which streams from below upward, its natural course, preferably seeks an outlet along the line of least resistance with unequal distribution and uncertain penetration of the articles as a result. Streaming over-steam, which we might designate the steam from above downward, is consequently the proper steam, while streaming under-steam, which travels in the opposite direction, is absolutely to be discarded in great as in small, when dealing with surgical steam sterilization of materials which are to be penetrated all through, unless these are uniformly packed—an unattainable requirement in practical life, where the sterilizing chamber is filled with articles of most different size, form and density as bandages, towels, sheets, cotton, etc., and which leave open spaces between them. Steam at rest also penetrates well, particularly when it is high, though not as expeditiously and thoroughly as the incessantly streaming one.

Concerning the condensation of the steam, it is of considerable importance that the materials to the greatest possible extent get the benefit of the contained moisture of the steam; the more moist the steam operates, the more it imitates boiling and the better it sterilizes. Condensation of the moisture is absolutely necessary and will take place when the articles are of lower temperature than the penetrating steam; the greater the difference, the greater is the condensation and the more wet the articles. For this purpose the quantity of water delivering the steam cuts an important figure. The greater the quantity of water boiled the greater is the amount of steam and the more abundant the condensation. Therefore the steam sterilizers should be constructed to hold a quantity of water proportional to the amount of articles and the size of the apparatus—half a gallon being appropriate for small sizes and one gallon for larger. For the same purpose we must provide for good fire—good, preferably double, non-sooting gas burners, powerful gasoline stoves or good kitchen fire; while alcohol or kerosene lamps are less suitable for larger sterilizers, they can be used with advantage for the small ones, for instance, milk sterilizers. Under abundant generation of steam the time of sterilization is shortened, the generation and condensation following rapidly, and outweighs the additional time required in heating up a larger amount of water. The highest degree of condensation is attained by conducting abundantly generated steam through coldest possible materials. It takes the steam, of course, longer time to penetrate a cold than a warm article, as the first condenses more steam than the last and at a lower temperature, and as this condensed moisture must again be vaporized by the incoming steam to advance further. In order to abbreviate the time it was formerly recommended to construct the steam sterilizer in such a manner that the contained articles could be heated up by dry heat before the steam was turned on; this would consequently highly facilitate the penetration by re-

ducing the condensation and time is apparently saved. Yet this heating up beforehand is largely a thing of the past: the time gained is lost in heating up the articles and, this is most weighty, we lose to a great extent the all-important advantages of an abundant condensation. It is a remarkable and at the same time welcome circumstance that the temperature during the condensation and the following evaporation of the condensed moisture increases beyond the original temperature of the steam and it rises higher the larger and more packed the apparatus is—up to 219° F. and even more. The reason of this can provisionally be indifferent; it is enough for our purpose to point out this happy occurrence. This increased temperature lasts about a quarter of an hour; when the condensation is complete, the condensed moisture again vaporized and the steam flows unburdened and free, the temperature drops to the normal. During the condensation and vaporization with their increased temperature the determining and essential sterilization takes place; later on the steam works with little or no moisture and therefore with little efficacy, if with any at all. At any rate the first fifteen minutes are more important than the same number of hours afterwards.

Concerning finally the saturation of steam or freedom from admixture of air, all agree that it is of much importance to have all air contained in the sterilizing chamber completely expelled, as heated air has a considerably less sterilizing power than steam. It looks very peculiar, that modern German and American authors, who in their books take special pains to emphasize this point, without hesitation construct, picture and recommend apparatus which in no way comply with the laws they themselves have subscribed to. It is an easy matter to expel the air completely from an apparatus constructed for streaming steam. The steam itself will effect this, provided it enters above and leaves below, since it, as above stated, is lighter than the air, remains on top of this and drives it out with a piston's action. If the steam enters below it will hurry upward through the contained air and leave above. It will certainly carry with it a good deal of air, but never completely, as the air is too heavy for it and it has not the power, abundance or uniformity. Under such circumstances it is no criterion, that every part of the sterilizing chamber shows an uniform temperature of 212 degrees F., as the retained air will be heated to the temperature of the steam. We have then in the same apparatus air at 212 degrees F. and steam at 212 degrees F. and this justifies me with great positiveness to insist that surgical steam sterilizers for under-steam are scientifically wrong and practically useless, at any rate, unreliable. We must vigorously demand that apparatus for streaming steam must be constructed for over-steam, whether they are large or small, stationary or portable. In apparatus for steam at rest the air must be expelled. This is attempted by a stop-cock on top, opened three or four times as the chamber becomes filled with high steam. The steam mass is then so considerable, powerful and compact that we reasonably expect to expel the air almost to completion, but not with positive certainty as is the case with over-steam.

After the above laid down principles for disinfection with steam we arrive at the result, that low, streaming, wet, saturated over-steam is surgically

perfect and that high, stationary, wet, saturated steam is not only surgically but also bacteriologically perfect. On either of these principles our surgical sterilizers must be constructed. The crucial question is, on what principle the most practical apparatus can be built? It is not very difficult to answer this question, when we consider that a sterilizer shall not only sterilize but that it shall also deliver the sterilized articles perfectly dry. French authors, who are so clever as to accuse German surgeons of relying upon inferior apparatus because they have adopted Lautenschläger's surgical sterilizer, while the Frenchmen employ Chamberland's bacteriologic autoclave, and forget that their sterilizers do not deliver dry materials and that their results do not outshine those of the Germans.

Chamberland's autoclave for high steam is viewed as a steam sterilizer, an ideal; viewed from a standpoint of a surgeon, it is far from it. It must be compactly built to withstand the high pressure; this makes the apparatus expensive and unfit for transport. It is impossible on the field. The autoclave is relegated to a stationary apparatus. Provisions necessary to measure the pressure and temperature, to make it tight and allow the escape of air and steam, complicate the otherwise simple construction and increase the expense. And, last but not least, when the sterilization is completed after one-half to one hour, according to the size of the apparatus, and the sterilized articles are removed they are moist and must undergo an extra process to become dry and fit for use. Even if the autoclave, which in my opinion belongs in the laboratory only, can be adopted and recognized in the larger hospitals with great means and facilities at their command it will be because of the above stated reasons, and can never be fitted for smaller hospitals, for individual surgeons and for the field.

Let us now, on the other hand, see how we can meet the designated requirements as regards sterilization, drying, transportation and economy in apparatus, constructed for over-steam. In the following illustration is pictured an apparatus which has cost me much money and much valuable time to bring to that perfection and simplicity I claim to be its principal virtues.

My sterilizer consists of three essential parts: A basin (A, the waterpan), an inner cylinder (B, the sterilizing chamber) and an outer cylinder (C, the hood). The basin and the inner cylinder form one piece, the outer cylinder another and these two parts are for transportation held together by means of a clasp. The bottom of the basin is perforated by a circular opening, an inch in diameter, corresponding to a similar one in the lower conical end of the inner cylinder; these two openings are seamed. The diameter of the inner cylinder is one inch less than that of the basin and the conical projection of the same begins at the level of the upper border of the basin, which is about three inches in height. At the junction of the inner cylinder and its cone is a wire diaphragm of galvanized iron. Between this and the opening below there is a square tin plate. Under the bottom of the basin is adjusted an iron plate, a quarter of an inch distant. The outer cylinder fits accurately within the basin; it is consequently nearly a half inch from the inner cylinder and it extends half an inch above the latter; it ends conically above in a short tube, fully an inch in diameter, for the

reception of a cork; it is provided with handles. The basin has a lip for filling and emptying not shown in the illustration.

Directions for use: Place the articles to be steam-sterilized in the sterilizing chamber, tightly or loosely packed as desired; adjust the hood, put in the cork, fill the water pan and place the apparatus over any good flame. When the water boils the generated steam will ascend in the narrow space between both cylinders and as the cork prevents its escape above and the water below, it must work its way through the sterilizing chamber and contained articles, leaving by the lower opening after having driven before it the air contained. Here it meets the glowing plate, which converts it into invisible, super-heated steam. That lively generation of steam occurs despite the fact that none is visible; we know it beforehand and it can be ascertained by lifting the cork. During the boiling some steam is continually condensed by the outer cylinder on its inside; the steam condensed in the conical part of the outer cylinder will not continually drop down on the contained articles because of conical form of this part, but will run back into

the basin. After completed sterilization, which requires from one-quarter to one hour, according to the size of the apparatus and the amount of packing, from the time the water boils, the steam contained in the articles must be expelled in order that it shall not moisten the contents, when these are removed and cooled. This is accomplished by removing the cork, regardless whether the flame be turned off or not, or the apparatus removed. All steam, both that given off by the water and that contained within the sterilizing chamber and its contents, will hasten to leave the apparatus through the upper opening and it will not take many minutes before the steam is nearly all gone and the articles dry. The articles nearest the diaphragm are first dried, both because the steam first leaves them and because hot air enters the sterilizing chamber from below to take the place of the departing steam. The iron plate under the bottom retains its heat for a long time and the air, which must pass over it to enter the apparatus, will be heated correspondingly. The uppermost layers of the articles will be dried last, since all the steam contained must pass through them; the close proximity to the steam gen-

erated from the water assists in keeping them slightly moist, but this can be remedied by emptying the water after completed sterilization. Larger apparatuses, which by their weight make emptying difficult, are supplied with an extra cover for the inner cylinder to protect the articles from drop. During the drying, which is accomplished whether the apparatus is over the flame or not, the temperature of the articles drops considerably below that of the steam—down to 170 degrees F. or still lower—despite that the inner cylinder is surrounded upon all sides by water and steam temperature of 212 degrees F. and despite that hot air of 400 degrees F. enters the sterilizing chamber from below this is the recompense for the increased temperature, which, as mentioned, takes place during the condensation and the vaporization.

As is made apparent the sterilizer constructed by me, originally devised for steam sterilization, is likewise an apparatus adapted not only for drying but also for sterilization by hot air, the last being mentioned under catgut. If the apparatus be placed over the flame without the cork in upper tube the generated steam will leave the apparatus through this. The inner cylinder will consequently be surrounded by water and steam at 212 degrees F., while no steam or moisture enters its lumen. At the same time a draught is brought about in the inner cylinder in the direction from below upward, as in any vertically placed pipe.

The air entering through the lower opening will consequently be heated by passing over the hot plate; the temperature of this air is about 400 degrees F. at the moment it enters the apparatus. As this temperature is scorching, the above-named tin plate is placed in its path midway between the opening and the diaphragm. This tin plate will absorb the heat and again radiate it; it acts consequently like a damper and at the same time as a radiator, with the result that the temperature at the level of the diaphragm will be about 100 degrees lower or 300 degrees F., a temperature which does not scorch, at any rate not in the time concerned. Under sterilization of catgut is mentioned how this temperature is reduced gradually as we approach the top, as the inner cylinder itself is only at 212 degrees F., the temperature of the surrounding steam, and this is refrigerating. In the upper part of the sterilizing chamber the temperature of the hot air is about 240 degrees F. The dry heat is subject to variations in the different apparatus; it is first of all dependent upon the strength of the flame, further on the thickness and size of the hot plate, upon its shape and its distance from the bottom of the basin, furthermore upon the diameter of the lower opening in the sterilizer, upon the size of the tin plate, upon the size of the apparatus itself, etc. I have originally con-

structed my sterilizer for steam and for hot air combined in order to dry steam-sterilized articles to a perfection not obtainable in any other apparatus. But when I found it was possible also to control dry heat I devoted my attention to construct a special one for sterilizing catgut also, while I have not paid any special attention in that respect to those apparatuses which are to be used for steam sterilization and drying only.

I would be pleased if I have been so fortunate as to convince you that my sterilizer is not only surgically perfect in scientific respect but that it also practically possesses material advantages. The simple construction secures a reasonable price; there are no stopcocks, regulators or safety valves; a thermometer is superfluous except for catgut; there are no solderings, which by melting when the sterilizer goes dry renders it useless; everything is seamed. It is consequently durable, especially when made of copper, and it is at the same time light and transportable. If it drops and becomes dented it is the work of a minute to straighten it out. The change from steam to dry heat is simply effected through a common cork, which is deposited in the lip of the basin when not in use. It is a matter of course that it is scientifically tested and has withstood this trial. Practically I never had any reason to suspect that it failed me. The model, which commends itself in the field, is illustrated below; it can be easily transported in a suitable wooden box.

It is deplorable that instruments can not be sterilized in steam without rusting; the steam can not, unfortunately, be rendered alkaline. Catcarrth has certainly demonstrated that instruments do not rust in steam when they are previously heated to 212 degrees F. before the steam is turned on. I have tried this method extensively and can verify the truth of Catcarrth's assertion, if we are very particular in heating and do not allow the instruments to be cooled off in the sterilizer after the sterilization. But I left this method as soon as I realized that boiling was so much more simple, and when I suspected that it was more than dubious that the instruments were disinfected by this procedure. If the instruments are of the temperature of the steam admitted no condensation will take place; the instruments will remain dry and consequently unaffected both by moisture and by rust despite that they are steamed. The instruments must be steamed while cold in order to be sterilized, and then they will rust. It is nowadays fashionable to construct apparatus for combined boiling of instruments and steaming of dressings. I myself have long ago cherished the same thought, but have arrived at the conclusion that instruments and dressings must be sterilized separately. It is an easy matter to construct apparatus for combined sterilization if we will employ under-steam, as Schimmelbusch and Beck have done. But I, for my part, will not agree to break with my own and at the same time universally recognized principles for the sake of such an insignificant trifle. Schimmelbusch, Beck and I have condemned the under-steam upon principle, and as far as over-steam is concerned, I have certainly some time ago in the *Medical Record* pictured an apparatus for combined boiling, steam and dry heat, but I do not recommend it for instruments anyhow, as the boiling pan will require too great dimensions so far as the transportable apparatus is concerned when they are to be made circular—the

most convenient and inexpensive form for steam sterilizers.

In conclusion, a few words in regard to our dressings which are particularly fitted for steam sterilization. They can in the course of half an hour be made ready for use in a transportable or smaller apparatus. In military service it is, however, very desirable to have them ready without notice. I have already demonstrated how we can always have ligatures and sutures at hand in sterilized form; I have not been able to do the same for instruments, while Bloch has happily solved the question for the dressings. He has proposed to wrap them up in blotting paper in double layer. Blotting paper is impermeable to microorganisms so long as it remains dry, while steam penetrates it with ease. We arrange therefore the materials in small packages and mark the quantity and quality of the contents on the outside. These packages are placed in the sterilizer, steamed and dried in the ordinary manner. To protect against moisture they should subsequently be placed in tin boxes. These packages will remain aseptic as long as they are kept dry; if in doubt, an additional sterilization is given. Anyone opens the outer blotting paper, while the surgeon or his first assistant handles the inner wrapper which holds the dressings. I believe that Bloch's method is eminently adapted to military surgeons, who must exercise their important and responsible work under exceptional and difficult conditions.

A CASE OF NON-OPERATIVE CURE OF ACUTE PYONEPHROSIS.

BY DR. ALEX C. WIENER.

CHICAGO, ILL.

Mrs. X., 28 years of age, had always enjoyed vigorous health. Six weeks before I saw her she had a miscarriage and unfortunately became infected on the removal of the fetus. Then, upon advice she underwent a laparotomy, because an extra-uterine pregnancy had been diagnosed. This, however, proved to be an error, and after three weeks she was sent home. Ten days later, by request of the sister of Mrs. N., a trained nurse, I was called, and found the patient with the appearance of a pyemic condition, extremely pale, blue lips, cold sweats all over the body, several chills daily, sleeplessness and loss of appetite. The temperature had gradually risen to 104 degrees; pulse 130, weak and intermittent; urine scant and very concentrated, passing eight ounces in twenty-four hours, and containing a small quantity of pus, after filtration through sugar, no albumin was found. Internal examination revealed an acute metritis and parametritis, forming an exudate the size of an orange in the right pelvis. The abdomen was soft in the lower part, considerable tension and extreme sensitiveness toward the right hypochondrium. In the right hypochondric region there was a tumor the size of a child's head, moving with the respiration and apparently connected with the right kidney, which led to the diagnosis of an acute pyonephrosis. I expected to be compelled to open the abscess and informed the relatives to that effect; but first I preferred to give Ozonate Lithia Water a trial, because of its formula: Lithia peroxyhydrate in White Rock Spring Water and charged with ozocarbonic acid gas, although I did not expect it to have much effect. The only therapy administered consisted of hot applications over the tumor, and two quarts of Ozonate Lithia Water daily, hypodermic injections of nitrate of strychnia. One thirty-second of a grain every three hours to overcome the critical condition of the heart muscle and milk diet. The result was the desired one. In three days the amount of urine increased to fifty ounces per twenty-four hours, containing a large quantity of pus. In eight days the patient was practically well, though still very weak, the pyonephrotic tumor having entirely disappeared.

This case clearly demonstrates that this water is a strong stimulator of the kidneys to secretion in renal disturbances. The great pressure from above is able to force a large quantity of pus out of the pelvis of

the kidneys in a very short time and dilute the pus to such an extent that it passes through the ureter without producing colic pains.

Since then I have treated numerous cases of acute cystitis with Ozonate Lithia Water, and all patients have remarked the immediate relief from painful and frequent micturition. Although I have not made chemical researches as to the secretion of urates under the treatment, there is a decided improvement experienced in all the different troubles based upon the overcharged condition of the blood with uric acid. The continuous use of this water after recovery can only have a beneficial effect, inasmuch as it would be preventing a recurrence of the disease.

A contra-indication to the extensive use of the water is the parenchymatous inflammation of the kidneys, as the Lithia, according to recent researches, is likely to stimulate the disease. On the other hand two or three quarts of the water are useful to wash out the kidneys and relieve the tubuli contorti from the presence of casts without being harmful. In cases of dropsy produced by heart disease, the use of the water ought not to be advised, as the amount of fluid embodied increases the work to be done by the diseased organ.

34 Washington Street.

REPORT OF AN EPIDEMIC OF TYPHOID FEVER AND THE USE OF THE WOODBRIDGE TREATMENT.

Read before the Portage County Medical Society, November, 1895.

BY JOHN J. ORTON, M.D.

HEALTH OFFICER, RANDOLPH, OHIO.

Gentlemen:—There is a rule in rhetoric which I think is called Pope's Rule:

"In words, as fashion, the same rule will hold,
Alike fantastic, if too new or old;
Be not the first by whom the new are tried,
Nor yet the last to lay the old aside."

This is a good rule to follow in the use of medicine as well as words. Nearly every mail brings us one or more circulars, singing the praises of some new remedy and it would be difficult and unwise to test them all. Being naturally conservative, and remembering the teachings of one of the now deceased professors of my Alma Mater to avoid "journal practice," it was with doubt and hesitation that I began to treat typhoid fever by the "Woodbridge treatment."

During September and October, our little village of about 250 inhabitants passed through one of the worst epidemics of typhoid fever in its history. Since May, 1895, twenty cases of typhoid fever have occurred in my practice. All but one, or possibly two, originated in this place. One came here sick from Cleveland, but not until toward the close of the epidemic, and one, a traveling salesman, became ill while away and came home; there is no way of telling whether his disease originated here or away, as he is often at home over Sunday.

Six persons have been sick with fever soon after leaving this place and five of these six have died. Three of the twenty cases under my care have died; two of typhoid fever alone, and one old gentleman of typhoid fever complicated with serious chronic diseases. At the beginning of the epidemic I searched the text-books in vain for some treatment that might prove satisfactory. All said that typhoid fever could not be shortened by a single day. Loomis, whose work on practice was the first I bought, and for whom

I entertain great respect and admiration, says: "The duty of the physician is to guide the disease, as far as he may be able, to a favorable issue and prevent injury to organs essential to life, keeping in mind that a certain definite period must elapse before this result can be accomplished."

Having read some of the articles on typhoid fever written by Dr. J. E. Woodbridge, of Youngstown, Ohio, I was favorably impressed with the results he reported from the use of his treatment, and wrote to him for instructions and obtained a supply of tablets put up by Parke, Davis & Co. according to his formulæ. Not being satisfied with the results I obtained, I went to Youngstown to see Dr. Woodbridge personally, but found that he was in Chicago. My journey was not in vain, however, for I was very kindly treated by Dr. M. V. Cunningham, who had charge of Dr. Woodbridge's practice during his absence and who told me all I wished to learn in regard to the use of the remedies used by Dr. Woodbridge.

Since my return I have had excellent results in the treatment of typhoid fever; all of my patients have improved under this line of treatment, some of them more rapidly than I dared to hope for. I have the pleasure to-day of showing you several charts which differ from those shown in the text-books. These charts show a step-like decline to the normal temperature, which, in most of them, is reached in two weeks or less. On one, the normal line is touched in ten days, although there was a slight fever in the afternoon for five days longer. One of them shows the normal line touched on the twelfth day of treatment, and sixteenth day of disease, and one shows the same result on the fourteenth day of treatment and seventeenth day of illness. All of these patients had the rose spots and other symptoms necessary to establish a positive diagnosis, and three of them were seen by other physicians who confirmed my diagnosis of typhoid fever. As yet I have not been able to obtain as brilliant results as Dr. Woodbridge reports, but have found that, if the medicine is perseveringly used, the temperature will invariably decline, delirium, tympanitis and other alarming symptoms will disappear and an early convalescence will follow.

The medicine must be pushed as fast as possible until the temperature falls below 100 degrees or these results will not be obtained. No. 1 should be given every fifteen minutes for twenty-four or thirty-six hours; then No. 2 every fifteen minutes to every half-hour right along until the temperature falls below 100 degrees. By the end of the first twenty-four or forty-eight hours of treatment the medicine should have produced five or six or more free evacuations of the bowels, and, should one tablet of either No. 1 or No. 2 not be sufficient to produce this effect, two or three or more may be given at each dose. The size and frequency of the dose may now be reduced so as to produce a gradual decrease in the frequency of the movements each day, until, by the time the temperature has touched normal, one or two free evacuations of the bowels occur during each twenty-four hours, and at no time should a day pass without this action being accomplished. About the third or fourth day No. 3 should be commenced and should be given every three or four hours until the temperature remains normal. If the temperature again rises No. 2 should be pushed energetically. Of course the patient must be closely watched, and if any symptoms of pyalism should occur omit the tablets for a day

or two and give a saturated solution of potassium chlorate, a teaspoonful every three hours, returning to the tablets as soon as possible.

I have met with one patient, a lady 46 years of age, who did not tolerate the mercury well. After three days' use of the tablets she suffered with slight pyalism and sore gums but it was not very severe. I stopped No. 2 and gave the potash solution for forty-eight hours. I then gave small doses of podophyllin, gr. 1-8 to 1-6, every four hours alternating with No. 3. She did well on this treatment. I believe that by the careful use of these remedies, or by a similar line of antiseptic treatment, more lives can be saved than by any other plan. Stimulants and tonics should be given if indicated, but with this treatment they will not be needed as often as by the older methods. Plenty of cold (not iced) boiled or distilled water should be given and the patient encouraged to take several swallows with each dose of medicine. Milk diet should be enforced and no solid food given until the temperature remains normal. If the patient has an aversion to milk, some good liquid food can be given, but milk should be taken also in smaller quantities than when used alone. The following report of two cases show how the medicine can be pushed:

E. J., age 6 years, began to complain October 20. On the evening of October 22 I saw him and found a

E. J., age 6 years.

temperature of 104 degrees. I gave No. 1 every half hour for thirty-six hours; then No. 2 every twenty minutes a part of the time and every half hour a part of the time until October 31 (nine days), when the temperature reached 99.8 degrees. The tablets were then given less often, and teaspoonful doses of liquid peptonoids, with creasote and guaiacol, were given every three hours. This patient was so young that I did not try to give No. 3, as I feared that he could not swallow the large capsules. On October 26 his temperature was 105 degrees, but fell day by day till it touched normal a few hours over fourteen days of treatment, and on the seventeenth day of illness. Although this boy took the tablets very often for nearly two weeks, castor oil was frequently given to obtain sufficient movements of the bowels.

On October 13, Mrs. O. H., age 71 years, first felt that she was not as well as usual. She had been assisting in the care of her daughter who came from Cleveland, five weeks before, sick with typhoid fever. On October 16 she was obliged to go to bed and her temperature rose day by day till it reached 101.6 degrees on November 19. Then I gave tablets of Dr. Woodbridge's No. 1 at 9 A. M., and gave them every twenty minutes until 10 P. M.; then every half hour till 2 P. M. on the 20th. The temperature then being

only 100.5 degrees, tablets were given every half hour till 5 P. M. The temperature then having risen to nearly 101 degrees, No. 2 was given every half hour till 9 A. M. on the 21st when the temperature was 99 degrees; No. 2 was given every hour till 2 P. M., then every half hour as the temperature was rising and continued till 10 P. M.; then every twenty minutes till 1 A. M. on the 22d; then every half hour till 9 A. M. At 9:30 the temperature fell to 96.6 degrees, but the pulse was 82 and good. Stimulants were given and hot applications made to the feet and limbs; her temperature rose to 100.2 degrees in afternoon. The next morning the temperature fell to 97 degrees and went to 100.6 degrees in the afternoon.

The temperature was sub-normal for three days and longer, and rose slightly above normal in the afternoon gradually having less departure from normal either above or below. Tonics and stimulants were given when temperature was below and Woodbridge tablets or capsules when above. This lady took the Woodbridge medicine seven days, when the temperature remained normal, or slightly below in the

Mrs. O. H.

morning. She told me that she nearly always had a sub-normal temperature when recovering from any sickness. This was an interesting case to me, as most text-books say that it is extremely rare for a person in advanced years to have typhoid fever. She had rose spots, tenderness over the bowels and enough other symptoms to leave no doubt of the correctness of the diagnosis.

Eight persons received the Woodbridge treatment with no death. In every case the effect of the medicine was plainly shown by a decline in the temperature and improvement in all symptoms. Those who received the treatment early had no dry tongue and but little tympanitis or diarrhea.

Twelve patients received other treatment with three deaths. No doubt deaths will occur under any plan of treatment, but I believe that the mortality from typhoid fever would be greatly lessened if physicians would use the Woodbridge treatment. I had excellent opportunities during this epidemic to test their efficacy, and, until something better is found, shall continue to use them in typhoid fever.

PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

PER ANNUM, IN ADVANCE \$5.00
SINGLE COPIES 10 CENTS.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 86 FIFTH AVENUE, CHICAGO, ILLINOIS.

W. H. LOWDERMILK & CO., WASHINGTON AGENT.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 86 Fifth Avenue, Chicago.

SATURDAY, FEBRUARY 1, 1896.

IS THE MEDICAL EXAMINER AN OVER-ESTIMATED
INSURANCE OFFICER?

The *Medical Examiner*, November, states that the insurance press has lately been discussing the value of the Medical Examiner in his relation to insurance, which is summed up by the *Guardian* in the proposition that perhaps, after all, the high value set upon the services of the medical examiner is an inflated one, and that his true merit should be quoted at a much lower figure. The *Underwriter*, also, has a short article upon the medical man in his insurance capacity, in the course of which it makes sundry charges and insinuations. One of these has reference to the organization of Medical Directors of Life Insurance, which is defended by the *Examiner* as a non-secret association, whose interests are in harmony with the companies to which its members belong; and the knowledge which these members obtain or extend through their association must be useful to their companies. This must especially be true in respect of rejected risks. But risks once rejected must not be assumed as of necessity and in a routine manner, to be destined to future rejection. "No company," says the *Examiner*, "would tolerate such a proceeding. Simply because a case has been rejected by another company is no reason for a further rejection, off hand, without due investigation." As a matter of fact, the rule is that every applicant for insurance is given an individual hearing, and companies have a right to make thorough preliminary inquiries about him before incurring the expense of an examination. The vast majority of applicants give this information themselves, as they are specifically asked in the application whether or not they have been rejected.

"No insurance examiner has a prejudice against a

symptom. Certain symptoms or signs indicate certain conditions, and according to the condition so will be the opinion on the case. He has no business to be prejudiced either one way or the other. He has a duty to perform, and a conscientious examiner will do it without fear or favor. He has no right to let his prejudice enter into the question, otherwise he is a hindrance, not a help to the business. Companies employ him for his supposed ability to detect or exclude conditions which render the applicant an unfit subject for insurance; or, in other words, a life or a case which, if accepted, would bring a loss instead of a profit to the treasury of the company. Insurance companies can not dispense benefits if their business is a losing one. The doctor is valuable to them in so far as he is an aid in the acceptance of risks which will prove a benefit or a profit to them, and in excluding those which are uninsurable."

How far an examiner may allow his personal and peculiar views, as to cardiac symptoms, or those referable to the lungs or the kidneys, to weigh in the rejection of candidates, is a question that may safely be left with the company to watch and determine. If a medical man makes a practice of accepting or rejecting a certain group of candidates, and does so contrary to the light of the present-day pathology, he is likely to have but a short official tenure. In other words, the true and best interests of the companies move along in parallel lines with those of their medical advisers; the judgment of the latter may be at fault at times; the medical examiners themselves may not always be of one mind regarding the interpretation of risks, but the net result can hardly be any other than a vindication of the claim of the *Examiner*, that the day has not yet come when the companies can dispense with their almost universally trusted and trustworthy examiner. The value of the latter to his company will possibly, in the future, be placed at a higher rather than "a lower figure"; for a higher grade of specialized training is year by year being undergone by the medical profession.

THE FEES OF AN EXPERT WITNESS.

We have heretofore adverted to the case of DR. J. N. DIXON, of Springfield, Ill., and in our issue of April 13, 1895, we published in full the opinion of JUDGE CREIGHTON. Our readers will recall that this case arose in a suit for damages for injury caused by a defective sidewalk, brought by Olive Purdy against the city of Springfield, Ill. DR. J. N. DIXON being called as a witness by the city, having no knowledge of the facts in the case, was called as an expert, and when asked a hypothetical question declined to answer on the ground that an expert witness is entitled to a different and greater compensation than an ordinary witness is allowed, and that an expert is not required to give expert testimony without compensation as an expert, unless a reasonable compensation shall have been paid or provided for; that he had not been paid nor offered anything for compensation for

his expert or professional opinion in the case, a fee of \$10 having been asked for by him and expressly refused. The judge of the Circuit Court of Sangamon County then demanded that the Doctor answer the question and on his continued refusal fined him \$25 for contempt of court. The Doctor thereupon appealed the case to the Appellate Court, and an opinion affirming JUDGE CREIGHTON's opinion has been handed down.

The opinion of JUDGE CREIGHTON was remarkable for its thinly veiled sarcasm, and its arrogant statements in regard to physicians.¹ "Physicians in this State," says this learned Judge. "are the favored children of the State; a department of the State government is maintained very largely for their benefit; they hold a license to practice their profession and practice by grace as well as by right, and are so hedged about and protected by the laws of the State, and by public opinion and confidence, that in five minutes of time a doctor may earn more than an ordinary laborer could earn in a day." Exactly what this very remarkable paragraph had to do with the case, except to show the bias of the Judge is not very clear, and we fear that if our legal luminary were placed on the witness stand and asked what department of the State government is maintained very largely for the "benefit" of the medical profession, he would cut a very sorry figure.

When a Judge on the bench descends to such an attack on the medical profession, he makes an unwarranted use of his position, and necessarily lessens respect for the opinions of his court. Such statements would answer admirably for a DOGBERRY, but have no place in the enlightened jurisprudence of the nineteenth century.

The text of the decision of the Appellate Court, the HON. GEO. W. PLEASANT, presiding justice, is as follows. It will be noticed that it is entirely devoid of the wild statements and absurd declamation which we have pointed out as characterizing the "opinion" of JUDGE CREIGHTON:

STATE OF ILLINOIS,
APPELLATE COURT THIRD DISTRICT.
May Term, 1895. Filed Dec. 2, 1895.
Docket No. 114. Agenda No. 103.

JOHN S. DIXON
vs.
THE PEOPLE, &c. { Error to Sangamon.

OPINION.

Per Curiam.

The appellant, a physician and surgeon, was brought into Circuit Court of Sangamon County by the ordinary process of subpoena to testify as a witness in behalf of the defendant in a case then pending against the City of Springfield, brought to recover damages for personal injuries which the plaintiff alleged she had received from a fall upon a defective sidewalk.

The appellant knew nothing whatever of the facts of the case, and he declined to answer a hypothetical question propounded to him calling for his professional opinion upon the assumed state of facts mentioned in the question, except upon the payment of a fee of \$10. He persisted in such refusal and the Court ruled he was in contempt and assessed a fine against him.

It is conceded the fee demanded was reasonable in amount

and no question is raised in the brief as to the power of the Court to inflict a fine as punishment for contempt in refusing to answer any question which the law required the witness to answer, and therefore the sole question presented is: Could the appellant, under the circumstances, lawfully decline to give his professional opinion without reasonable compensation? As far as we are advised the question has never been directly passed upon in Illinois.

Nor can any rule be drawn from the currents of judicial decisions in other jurisdictions or from a concurrence in the views of text writers, so widely at variance and so directly in conflict are the opinions of different courts and law writers upon the subject.

It is not contended the reasonable compensation demanded by the appellant could be taxed as costs, but that the party desiring his professional opinion should be required to compensate him therefor, before the law should compel him to express that opinion for the benefit of such party. We think the court ruled correctly in holding the law required the witness to answer the question.

The statute has fixed the compensation to be paid all witnesses and the law requires every person without regard to his calling or engagements, to appear as a witness when duly subpoenaed and to accept as full compensation the statutory allowance however inadequate it may be.

The administration of justice in the adjustment of the contentions growing out of the business affairs or concerning mere private personal property or property rights of its citizens is one of the most important sovereign duties devolving upon the State. Upon the performance thereof depends the public peace and tranquility, and the safety and security of the property, reputation, person and family of every private citizen. Every citizen is therefore deeply interested in the proper discharge of that duty. It can only be discharged through the medium of judicial tribunals. Without the power to compel witnesses to attend and disclose facts in their knowledge pertinent to these contentions these tribunals are powerless to perform their functions. No distinction can, we think, be drawn between different kinds of knowledge, nor can a witness decline to make known facts which have come to his knowledge either by observation or study and experience, upon the ground that he can use such facts or knowledge for his pecuniary benefit in the business affairs of life, when the disclosure thereof is important to the attainment of justice in the courts.

No reason is perceived why compensation beyond that fixed by the general laws of the State should be allowed to this class, or to any one class of experts, unless it is allowed to every other class, of which there are many—some works on expert testimony enumerate as many as seventy classes of expert witnesses. To hold each member of these different classes of witnesses may lawfully demand that litigants shall arrange for the payment of reasonable compensation before he can be compelled to disclose in open court facts in his knowledge relating to the right and justice of causes there pending for determination would be impracticable and would often operate to subject a litigant to financial burdens so great as to practically deny him a hearing in the courts, would tend to make the administration of the law depend upon the financial ability of the suitors to compensate witnesses in order to have the benefit of facts in their knowledge, and to bring such testimony into discredit as having been purchased, and to attach scandals and grave suspicions to expert witnesses and expert testimony. Nor does the rule requiring experts to testify for legal fees deprive the witness of his property for public use.

Knowledge gained by study, observation and experience is not property within the meaning of the word as used in Section 13, Article 2 of the Constitution, wherein it is provided that private property shall not be taken or damaged for public use without just compensation. The word in its appropriate sense means tangible things and rights which accompany or are incident to the use, enjoyment or disposition of such things. (See authorities collected in Note 1 to page 284, Vol. xix, Amer. and Eng. Ency. of Law.) In *C. W. F. R. R. Co. vs. E. C. R. W. Co.*, 115 Illinois, page 385, it was said: "Property itself in a legal sense is nothing more than the exclusive right of passing enjoyment and disposing of a thing." The ordinance of 1787 has no operative force in this State, except so far as its principles are embodied in the Constitution.

The People, etc. vs. Thompson, 155 Illinois, page 451.

The judgment is affirmed: Affirmed.

That there is conflict of opinion the court clearly states, and we understand that Dr. Dixon has taken an appeal to the supreme court of Illinois.

HON. JOHN A. STERLING, in an article in this Jour-

¹ See the text of this opinion in this JOURNAL April 13, 1895, p. 571.

NAL March 17, 1894, p. 381, states: "It is the prevailing rule that the expert witness is entitled to demand and receive adequate compensation for his opinions on the stand; and he can not be required to speak until it is assured. This applies only where he is called to give a professional opinion on a scientific question."

The opinion of HON. W. A. PURRINGTON, of New York,² so clearly expresses the existing situation in this country on this point, that we reproduce it.

The rule as to the fees of expert witnesses varies with the jurisdiction. In New York, although under general subpoena a physician must of course appear in court and testify to facts of the case within his ordinary observation, he will not be compelled to give his opinion on matters of skill and science. And therefore it is proper for the district attorneys to employ medical experts on behalf of the people. The fact that an expert has received a large fee does not make his testimony incompetent or afford ground for a new trial. But this rule of compensation is not the same, however, in all jurisdictions, and the contrary was held in a laboriously argued Alabama case. Some States have regulated the matter by statute. Thus, in Minnesota the judge is authorized to allow an expert witness "such fees or compensation as may seem just and reasonable," and it might seem, therefore, that such a witness might refuse to testify until he received at least the promise of what he thought a just and reasonable fee. But the supreme court held, approving the reasoning of *ex parte* Dement, that this provision of law had reference to an allowance to be made after the witness had been dismissed, not before. In Colorado, if the expert witness testifies under subpoena without making an agreement in advance for his compensation, he is only entitled to statutory fees. The Indiana Code of Civil Procedure provides for compelling an expert witness to testify without extra compensation. But prior to the enactment of this rule in 1881, the courts of that State had laid down the same rule as in New York. The English rule is that one called as a witness to give his opinion on a subject with which he is peculiarly conversant from his employment in life, is not bound to testify unless the party calling him "pay for his time," and in a comparatively recent case an auctioneer was said to be a professional witness and not bound to testify even if sworn, until his fee, expenses, or compensation for time at a guinea a day, were paid.

Since this work appeared the Arkansas supreme court has decided a case, Jan. 26, 1895, but this was a criminal case and the question turned on the Arkansas statutes.³

Should the supreme court of Illinois affirm the opinion of the lower courts in the case of DR. DIXON, the necessity will again be emphasized for supporting the ILLINOIS STATE MEDICAL SOCIETY in its appeal to the legislature for a proper statute for regulating this matter, and whatever may be the result of this appeal to the highest State Court, DR. DIXON is deserving of the highest praise from the profession of his State for the pluck and energy with which he has fought against the unjust ruling which placed him in technical contempt of court.

THE ETIOLOGIC RELATION EXISTING BETWEEN CERTAIN NEUROSES AND DIET, AND ITS THERAPEUTIC APPLICATIONS.

Adopting the comprehensive definition of CHOMEL as the simplest expression of what we mean by disease, that it is "the occurrence of an obvious disorder, either in the material disposition of the constituent

parts of the living body, or in the exercise of functions," it is evident from our knowledge of cellular pathology, that errors of nutrition must necessarily play an important part in the causation of disease. This, as a doctrinal teaching, has long been accepted by clinicians; but there is still lacking in medical practice evidence of a clear knowledge of the relationship existing between special forms of disease and diet and also a want of agreement as to the application of the principles of dietetics in the management of certain maladies, which are mainly attributable to nutritive disturbances. When ABERNETHY in his blunt phrase declared that "three-fourths of all diseases are caused and can be cured at the table," he expressed a thought which has entered the mind of every experienced and observing physician. The popular belief that food may exert a pathogenic influence, which is embodied in the saying, "What's one man's meat is another man's poison," could scarcely have a better exposition of its scientific foundation than was given by HIPPOCRATES in one of his aphorisms: "Wherefore, I say, that such constitutions as suffer quickly and strongly from errors in diet are weaker than others that do not; and that a weak person is in a state very nearly approaching to one in disease; but a person in disease is the weaker, and it is therefore likely that he should suffer if he encounters anything unseasonable."¹ In other words, just as a man may have a congenitally inadequate liver or kidneys, so he may have congenitally inadequate digestive organs. This is a fact which strictly speaking does not belong to dietetics, but which must not be lost sight of in arranging dietaries for individual instances of disease. This is a trite observation, but it will bear repeating. Although physiologic experiment has shown that the brain and spinal cord apparently, of all the soft parts, endure privations the best and relatively suffer less loss of weight during prolonged abstinence from food, it is true clinically that altered innervation is one of the earliest symptoms of disturbance of nutrition. Some years ago OLIVER WENDELL HOLMES directed attention to the influence of food upon vital phenomena in the following characteristic style: "Most assuredly I do believe that the body and mind are influenced by the food habitually depended upon. I am persuaded that a too exclusively porcine diet gives a bristly character to the beard and hair, which is borrowed from the animal whose tissues these stiff-bearded compatriots of ours have too largely assimilated. I can never stray among the village people of our windy capes without now and then coming upon a human being who looks as if he had been split, salted and dried like the fish which has built up his arid organism. If the body is modified by the food which nourishes it, the mind and char-

² A System of Legal Medicine, by Allan McLane Hamilton, New York, 1894.

³ See Jour. Amer. Med. Assoc., June 22, 1895, p. 991.

¹ Sydenham Society's translation.

acter very certainly will be modified by it also. We know enough of their close connection to be sure of that without statistic observations to prove it." SHAKESPEARE makes Sir Andrew Ague-Cheek incidentally express much the same opinion in "Twelfth Night": "Methinks, sometimes, I have no more wit than a Christian or an ordinary man has; but I am a great eater of beef and I believe that does harm to my wit."

Coming now to the etiologic relation existing between certain neuroses and diet, it is to be observed that neurasthenia and the peculiar state of the nervous system inappropriately termed hysteria, are curable by the WEIR-MITCHELL plan of feeding and rest, on the lines laid down in his booklet on "Fat and Blood, and How to Make Them." Epilepsy is to a large extent a dietetic disease; at least it has been claimed, on good authority, that a non-nitrogenous diet alone without drugs will bear better results than the bromids without restriction of diet. Similarly in the treatment of delirium tremens, the late J. HUGHES BENNET becoming convinced of the inutility of tartar emetic, opium and other drugs, abandoned them entirely and gave nothing but nourishment as soon as the patient could take it, the result being, in his own words, "all the cases that enter my wards recover." The delirium of low fevers, according to the teachings and practice of DA COSTA, is very often due to debility and is an indication for increasing the nourishment. The use of a non-stimulating diet is required in the treatment of chorea, night-terrors and other manifestations of a neurotic inheritance in young children. Asthma, considered as a reflex neurosis, is closely allied to epilepsy and requires careful supervision of the diet. The late DR. RANDOLPH, of Philadelphia, conferred immunity from attacks for months upon an inveterate asthmatic subject, by the administration of predigested or peptonized food. The relation of cause and effect was shown by the fact that whenever the patient would return to his ordinary table diet the paroxysms would reappear. It is a matter of common observation that a heavy supper or indulgence in certain articles of food are liable to bring on an attack in a patient having the asthmatic predisposition. Neuralgia is now often interpreted as the cry of a nerve for better nourishment, and food is given the precedence over anodynes in the treatment. Closely related to this is the subject of visceral neuroses. The late PROF. WILLIAM GOODELL once said to his class, "Gentlemen, the crying medical error of the day is, in my opinion, the mistaking of nerve disease for womb disease." The form of nerve disease which he particularly referred to was that which has been so successfully treated by the WEIR-MITCHELL method, to which allusion has already been made. There can be little doubt that many women who have been

subjected to gynecologic operations and have recovered, owe their recovery less to the mutilation they have undergone than the strict regimen and good care which attended the operation.

The recognition of alcohol as a factor in many neuroses unfortunately does not always direct us to success in treatment, because when the case comes under observation the lesions are so far advanced that their repair and restoration is impossible, although their progress may be delayed and the morbid processes held in abeyance. Kakké or beri-beri, a form of multiple neuritis, has been shown by DR. TAKAKI to be caused by a rice diet, where the rice is of inferior quality and partly spoiled. Its nature being recognized, beri-beri has been banished from the Japanese navy by diet-regulation, in the same way that scorbutus has been driven from ships of other civilized nations.

In the treatment of insanity, while admitting the underlying neurotic predisposition, it is universally acknowledged that diet is a potent aid to recovery. In a recent paper DR. KIERNAN states that in acute confusional insanity, the treatment consists in "proper nutrition, quiet and relief from agitation, psychoses of this type being due to systemic exhaustion and not to toxemia." If, as has been asserted by DR. THOMAS MAYS, pulmonary phthisis is less an infectious disease than it is a neurosis, the importance of food in the treatment of consumption receives an additional emphasis.

It is worth noting that the yolk of egg contains lecithin, a form of phosphorized fat, which is very similar in composition to the characteristic proximate element in nerve substance and, therefore, egg-yolk is one of the most important articles of food for the class of cases under consideration, being convenient, and, when given with milk or wine, usually acceptable to the patient, and also easily assimilated. The caffeine-bearing group of stimulants, coffee, tea, cacao and kola, are habitually used as articles of diet and their deprivation during illness may produce symptoms of nervous disorder, as pointed out by DR. I. N. LOVE, in a very practical paper on "Coffee," read before the Mississippi Valley Medical Association in 1891, in which attention is directed to the clinical fact that restlessness, insomnia and other nervous symptoms may be attributable to the withdrawal of some accustomed stimulant rather than to the influence of disease.

INFLAMMATORY AFFECTIONS OF THE COSTAL CARTILAGES.

The affections of the costal cartilages are but little known. The majority of our text-books and systems of surgery do not touch upon the pathology of the costal cartilages. RIEDINGER in his article in volume XLII of *Deutsche Chirurgie* devotes the larger part of

one page to the tuberculous chondritis and emphasizes the necessity of the most thorough treatment because the process has a very marked tendency to return. DITTRICH¹ describes, in 1893, sixteen cases of tuberculous chondritis from PROFESSOR ESMARCH's clinic. HELFERICH² wrote about costal chondritis after typhoid fever in 1890, and additional scattered references to this subject may be found here and there in the literature. The paucity of the literature on the subject, the nevertheless undoubted frequency of costal chondritis, and the theoretical and practical interest in this important part of the pathology of cartilage, led PROFESSOR BERG, of Stockholm, to publish some very valuable results of his clinical studies in this subject.³ BERG has treated thirteen hospital and three private patients for inflammatory processes in or connected with the costal cartilages. Four additional cases placed at his disposition by professional friends bring the total number of the cases studied by him up to twenty. Of these, fourteen were men, six women. As to age, one case occurred in the second, five in the third, three in the fourth, six in the fifth, and five in the sixth decennium.

Concerning the etiology, one of BERG's cases, a tuberculous chondritis, is very instructive because it shows very clearly that traumatism upon two separate occasions and involving separate cartilages is followed in each instance by tuberculosis in the cartilages subjected to injury. The essential cause of costal chondritis is, of course, some form of microbic infection. In all of BERG's cases, except two, the patients presented themselves with fistulous openings, so that a bacteriologic examination was omitted. In one of two non-fistulous cases the typhoid bacillus was present in pure culture, and in a new case observed during the printing of the article, the bacillus coli communis was present in pure culture. Studying his cases carefully from a clinical point of view, but with special reference to the etiologic factors present, BERG separates the following groups: 1. Tuberculosis. In seven of the twenty cases the process was undoubtedly tuberculosis; in only one could the process be said to be due to direct extension, namely from the sternum; in the others the disease seemed to be isolated. In four of the seven cases there were distinct pulmonary signs of tuberculosis, but any evidence showing the direct extension of the process from the pleura to the cartilages was not obtainable. Tuberculous chondritis may occur as the only expression of a tuberculous infection in otherwise healthy individuals. 2. Typhoid fever. This disease preceded the development of the chondritis in seven cases; in one case the chondritis began during the actual attack; in four the first signs of the cartilage affection developed in from four to six weeks after the

beginning of the typhoid fever; in two the time that elapsed was much longer. As already stated, in only one of these seven cases was there a bacteriologic examination and this showed typhoid bacilli only. 3. Syphilis. In one case a syphilitic perichondritis gave rise to the symptoms that led to surgical interference. 4. Septic infections. In four cases the connection of the chondral process with common forms of septic infection seems natural; in one case the chondritis developed eight days after a lobar pneumonia; in another case this relation to pneumonia was a little less striking; in the third case of this group the pneumonia developed on the day after the operation of laying open a fistulous tract that led to an abscess behind the fourth right costal cartilage; the fourth case seemed to be due to a general acute infection accompanied with acute nephritis.

The course and the symptoms of costal chondritis seem quite similar in the various etiologic groups. A marked chronicity seems to be quite general. The disease begins with spontaneous pain or limited tenderness in the chest wall, sometimes accompanied with a local swelling. The pain is described as stitch-like. The tenderness is often sharply confined to the precise area in which the operation subsequently discloses a focus in the cartilage and this may therefore be an important early diagnostic symptom as was the case in one of BERG's cases. The relation as to time between the pain or tenderness and the development of a visible or palpable swelling is, of course, variable. The swelling is usually quite hard at first, often peculiarly flat and distinctly connected with the underlying cartilage. Sooner or later the skin becomes red, the swelling soft, often very extensive, and spontaneous evacuation may occur. The fistulae that result invariably require surgical treatment in order to heal definitely. It is self-evident that the external opening of the fistula may be located far away from the primary cartilaginous focus.

The microscopic changes seem to point to the perichondrium as the seat of the first and earliest changes in the majority of the cases. In four of BERG's cases there was abscess formation underneath the cartilage lying either upon the pleura or the pericardium. The process has a distinct tendency to spread in the wall of the thorax and to involve more than one cartilage, although the possibility of a primary infection of many cartilages at the same time can not be denied. In the twenty cases of BERG, twelve showed only one cartilage to be attacked; four cases showed two, two cases showed three, and in two cases four cartilages were involved. The distribution of the process in the various cartilages is as follows:

Costal cartilage, number	II	IV	V	VI	VII	VIII	IX	X
Number of times involved.	1	2	6	5	8	6	2	1

The naked eye examination showed in all cases

¹ Festschrift z. Esmarch, 1893, p. 247.
² Centrbl. f. Chirurgie, 1891.
³ Nord. med. Ark., 1895.

except the one of syphilitic perichondritis that the perichondrium, as well as the cartilage, present distinct changes. The perichondrium is thickened and may be either abnormally loosely or abnormally firmly attached to the cartilage. In one case there was a distinct osteophyte attached to the perichondrium. In the cartilage itself the following gross changes were observed: Multiple, carious foci of destruction proceeding from without, due most likely to newly formed vessels and papillary outgrowths of granulation tissue from the perichondrium, and also central foci of disease consisting of cavities with irregular walls lined with granulation tissue and containing very minute cartilaginous sequestra or degeneration products; occasionally long channels may run from the central focus to the abscess in the soft parts. In only two of BERG's cases did the sternum or the ribs show any osteomyelitis; in all the other cases the process was confined to the cartilages. In addition to foci of disease the cartilage may show more diffuse changes, being either very soft or abnormally hard and brittle, and often of a distinctly yellow color. The description of the histologic changes including the interesting study of metaplastic processes has been reserved for some future time.

The diagnosis may be difficult. Muscular rheumatism, pulmonary and pleural lesions and intercostal neuralgia might readily be inferred to be present during the early stages of the chondritis before swelling had appeared. Even after the development of the swelling the disease might be confused with tumors of various kinds, gummas of the muscles and inflammations limited to the soft parts of the chest wall. After the formation of fistulous passages the diagnosis would seem easy, especially when the probe leads to the cartilage, but the passage may be tortuous and lead to a carious focus on the deep surface of the cartilage. Careful examination as to the salient points in the history of the process is valuable. The early confinement of the pain or tenderness to a definite cartilage from which a swelling may subsequently have developed and other features that may be elicited are all important from a diagnostic point of view. The bacteriologic examination of the contents of the abscess may throw much light upon the process, and the fact that symptoms of ordinary tuberculous or other form of chondritis may be produced by syphilis should not be forgotten.

Finally BERG concludes his instructive study with the following summarizing conclusions in regard to the operative treatment:

1. Operation should be made as early as possible as soon as the diagnosis is made. Operation may be necessary in order to establish a definite diagnosis. If there be any reason to suspect syphilis antisyphilitic treatment should first be instituted.

2. Evidement may bring the process to a standstill,

but usually only after repeated efforts, and knowing the exclusiveness and multiplicity of the changes in cartilages it is probably best to substitute typical resection for evidement.

3. In the greater number of cases the entire cartilage should be resected, including one or two centimeters of corresponding rib. But fast rules can not be laid down, as each case must be treated according to the indications presented, the location, nature and extent of the lesion being the essential guiding points.

4. The changes in the soft parts must be thoroughly removed in the tuberculous cases. In other abscesses the fistulous passages and the cavities must be thoroughly divided.

5. Aseptic wounds are difficult to obtain, especially in the cases with preëxisting external openings; consequently, attempts at securing primary union should be limited to the most favorable cases; secondary suture or open tamponade is the after treatment that in general promises the most favorable results.

PHYSICIAN AS WITNESS TO WILL WAIVES SPECIAL PRIVILEGE.

The California Code of Civil Procedure provides that "a licensed physician or surgeon can not, without the consent of his patient, be examined in a civil action as to any information acquired in attending the patient which was necessary to enable him to prescribe or act for the patient." But in making his attending physician a subscribing witness to his will, the supreme court of California holds, in the case of MULLIN'S Estate, decided Dec. 3, 1895, that a testator waives the privilege, and invites a full and proper examination of the matters and facts upon which his lips would otherwise have been sealed. Upon direct examination, the jury, in this case, was informed that the witness was a physician and surgeon, with years of experience and practice, and that he was the physician who attended the testator in his last sickness. Then, for their enlightenment, he was asked his opinion of the mental condition of the testator at the time of the testamentary act, and answered that the latter was of sound mind. The answer of necessity involved the use of the intimate knowledge acquired by the physician in prescribing for and treating his patient. It would be absurd to continue the court, to say that it was to be limited to the outward seeming and appearance of the patient at that particular moment, or, in other words, that the witness would have been justified in answering, for example, that from external appearances, and judging as a layman, his opinion was that he was of sound mind, but that using his professional skill and knowledge and intimate acquaintanceship with the patient acquired as his physician, his opinion was that he was mentally incompetent. Having answered that in his opinion the man was of disposing mind

there were open to the cross-examiner two fields of inquiry: First, the soundness of the witness' judgment, or, in other words, his qualifications as an alienist; and second, the character of the patient's infirmities—that is to say, the facts and circumstances upon which the judgment was exercised and the conclusion reached. Here the witness was interrogated, upon cross-examination, as to the character of his patient's affliction, which appeared to be serous apoplexy, resulting in hemiplegia, and showing that the brain is involved and affected by this disease; likewise, that the accompanying paralysis evinced itself upon the Thursday preceding the Monday upon which the will was executed and the testator died. In addition, the witness was interrogated as to the disclosures which the autopsy made of the physical condition of the deceased, and finally he was subjected to a cross-examination, keen and comprehensive, touching his professional learning and qualifications, and as an expert. This cross-examination, the court holds, was confined within the prescribed bounds, and was strictly proper.

CORRESPONDENCE.

Castration as a Treatment for Crime, not as a Punishment.

AUSTIN, TEXAS, Jan. 21, 1896.

To the Editor:—In your editorial comments on my paper which was read at the recent meeting of the Chicago Medico-Legal Society (see issue of January 18), I regret to see that you misapprehend its entire trend and object. Surely, you did not read it. You convey the impression that its object was to advocate castration of sexual perverts as a punishment; whereas the subject of sexual perverts was scarcely alluded to, and I distinctly disclaimed, in the very first paragraph, all idea of punishment; deprecate further along, that our penal system is based upon the ancient idea of revenge, and that its chief end seems to be punishment. And, again, I say, "punishment should have no place in a civilized code." (You must have had in mind my paper on sexual perverts which was read at the Medico-Legal Congress in 1893.) Moreover, nothing was said in this paper about castration except incidentally as a factor in the reform advocated, to be made available in certain conditions named. You are away off, and have unwittingly done me an injustice by ascribing to me sentiments foreign to the paper, and then saying the consensus of opinion was opposed to them.

The paper was a plea for reform in criminal jurisprudence, based upon facts which go to show that our statutes are not only inefficient—assuming that the aim and object sought is the protection of society and the repression of crime—but that our methods of executing them contribute really to the increase of crime and criminals; that the cause of lawlessness as witnessed in occasional lynchings, is the outgrowth of this inefficiency; that the people see that the law, even when rigorously enforced, does not afford them protection, but, on the contrary, crime, and especially, rape, is on the increase, and it is the feeling of insecurity that drives them to seek by other means the protection of home and family. A plea was made for a discrimination or classification of criminals, based mostly upon the recent researches of Lombroso, who has shown that a large percentage of criminals are born so, the victims of heredity and environment, and are alike irresponsible and irreclaimable. This class I would regard as permanent enemies to society,

and advocate their permanent sequestration—making them labor for their support and the benefit of that society whose privileges they have forfeited, and taking away, along with all other rights) that of procreating—inflicting upon a world a progeny, likely at least, to be criminal. And, with due deference to the learned legal gentleman who sneeringly said that "castration might do for Texas, but it would not be tolerated in an enlightened State like Illinois" (a remark not called for and worthy of a small mind), I will say that, unfortunately all the born criminals are not old men. But his objection that castration would be detrimental to moral character in the connection here stated, is too absurd; injure the character of a habitual, irreclaimable criminal!

Regarding all other criminals, the object of treatment or management should be reformation and restoration to society. This can be done in a very large number of cases; and the discipline should be instituted and executed under the supervision of intelligent medical men. It should be based upon, first, a correct diagnosis of each case. If of a reformable class, reform him: and the first step advocated was, to lift him above the environment calculated to harden him.

In brief, I endeavored to show that our penal system, based as it is upon the obsolete idea of revenge, retaliation, "an eye for an eye, a tooth for a tooth," is wrong and, naturally, ineffective: that as opinion has changed as regards insanity and inebriety, both of which were formerly punished as crime, so physicians are beginning to realize that crime in the habitual criminal is a disease and calls for treatment and not punishment. While I would not go so far as to say that all crime is the expression of a diseased state of mind, there is no doubt that much of it is, and the distinction between the state of the born criminal and moral insanity, if any, is too fine to be always recognized.

I pointed out the reluctance with which those who are intrusted with the making of statutes—for the most part persons who know nothing of the requirements of sanitary law—receive advice or information or suggestions; and ascribed as one reason, that there is no source whence the necessary knowledge can be obtained. I advocated, therefore, the creation by Congress, of a Department of Public Health, a repository for all knowledge bearing on health, whence it could be disseminated and utilized in the reconstruction of our statutes to bring them more in accord with the science of the day and a more enlightened civilization.

I regret that you did not read the paper more understandingly, because had you done so, I believe that you could not do other than endorse much that was there presented. It is only a matter of time; the changes that have taken place with regard to the management of the insane and the inebriate will sooner or later take place with reference to crime and criminals, and they will be managed more in accord with the dictates of humanity than at present. The great evil, next to the inefficiency of the penal code to fulfill its ends, is the indiscriminate treatment of the young and old, the born criminal and the first offender. A young man commits a crime through impulse and immediately repents and would give worlds to undo it. He is treated with all the rigorous severity that is meted to the hoary headed criminal. Very respectfully yours,

F. E. DANIEL, M.D.

Poisoning by Acetanilid.

QUINCY, ILL, Jan. 19, 1896.

To the Editor:—In our JOURNAL of Jan. 18, 1896, page 144, reference is made to a report in the *Virginia Medical Monthly*, by Dr. Ben. H. Broadnax, on the use of acetanilid. Having recently had in my own practice two cases of acetanilid poisoning, one terminating fatally, I can not, therefore, indorse Dr. Broadnax's recommendation for the use of this drug, particularly in new-born infants. A few weeks ago I prescribed for a

babe of four days, suffering with an erythematous inflammation of the skin of the nates, thighs and groins, a powder composed of equal parts of subnitrate of bismuth and acetanilid. During that afternoon and night the powder was dusted upon the inflamed areas three or four times. On the following morning the babe was found deeply cyanosed, and died a few hours later.

Before realizing that acetanilid was the cause of death in the case just noted, I prescribed the drug for another infant two days old. One application of the drug was made to the nates and thighs of the second child, about 10 P.M., and on the following morning this babe was also deeply cyanosed. Twenty-four hours later it had fully recovered from the toxic effects of the drug.

That acetanilid is not absolutely safe for external use in adults see reference in *N. Y. Med. Jour.*, Jan. 11, 1896, page 63, to a report in the January number of the *Yale Med. Jour.*, by Dr. William H. Carmalt, on "The Toxic Effects of Topical Applications of Acetanilid." The patient, a girl 18 years old, was suffering with an ulcer which had resulted from a burn over the larger part of the hand, in which there had been profuse suppuration. Powdered acetanilid was applied every four hours for twenty-four hours, when symptoms of cyanosis were observed. The employment of the drug was immediately discontinued and in twelve hours the symptoms disappeared." I have thus written that other physicians may guard against having a similarly unfortunate result from the use of acetanilid.

CHARLES W. ROOK, M.D.

Treatment of Obstruction of Lachrymal Duct.

DALLAS, TEXAS, Jan. 25, 1896.

To the Editor: Dr. P. Richard Taylor, of Louisville, Ky., read a paper before the Falls City Medical Society, entitled, "Dacryocystitis," published in the *JOURNAL* of Jan. 4, 1896. In this paper, the Doctor makes the unconditional assertion that probing the lachrymal duct for stricture is a failure, and that there is but one successful treatment, and that by a tube devised by himself. The Doctor distinguishes himself by giving us an instrument which seems almost indispensable in certain cases, to be mentioned later. My object is not to condemn his treatment, but to defend probing, which he brands "a failure." Inasmuch as I have never had a failure in an uncomplicated stricture, I must take issue with the Doctor. In all cases of complete stricture, I open up the duct with a knife and follow this with a probe as large as, in my opinion, is justified. Beginning on the second or third day, I inaugurate a series of probings every two or three days, at first, gradually increasing the interval between probings, from two to sixty days, which is kept up for some time after I consider the case well. When the obstruction is incomplete, I seldom use the knife to open up the entire duct, beginning probing at once with the smaller probes, sometimes increasing two or three sizes at one sitting.

The class of cases that seems to me to especially indicate Dr. Taylor's treatment are those stubborn cases characterized by contraction of the skin and mucous membranes. In such cases we often find a tendency to ectropion. These cases are exceedingly tedious.

When there is necrosed bone from sloughing or long continued suppuration, or injuries, no treatment is effective without first removing the necrosed bone. The cause in every case should be sought and, if possible, removed.

HENRY W. WANDLESS, M.D.

PUBLIC HEALTH.

To be Taught in Tennessee Public Schools. In addition to the branches in which instruction was given in the public schools of Tennessee, it was in 1895 enacted that physiology and

hygiene, with special reference to the nature of alcoholic drinks and narcotics and smoking cigarettes, and their effects upon the human system, shall also be taught as thoroughly as other required branches.

Restrictions upon Sale of Cigarettes. In order to provide for the better protection of the public health, the legislature of the State of Washington in 1895 enacted that it shall be unlawful for any person to sell cigarettes made of tobacco in combination with any substance or material, covering or wrapper, or containing any substance or material other than tobacco, until he shall have obtained a license therefor, and the applicant for such license must make oath, to the best of his knowledge and belief, that the cigarettes intended to be sold do not contain any injurious drug, or other deleterious matter, and that he will not knowingly sell any cigarettes containing any such injurious drugs, narcotic or other deleterious matter. It is also made unlawful to sell any cigarettes to minors under 18 years of age.

Cholera in Sand-Ballast. The Japan correspondent of the *New York Herald* writes as follows of the possible dissemination of cholera by sand-ballast: "Dr. W. F. Arnold, of the United States war ship *Petrel*, who was detached some months ago and directed to make a thorough investigation and study of the recent cholera epidemic in Japan, has returned to Yokohama from Shimonoseki. He reports that the quarantine service at Shimonoseki was most excellent, but the bacteriologic research quite indifferent. He got trace of one transport steamer which brought an unusual number of cholera cases from Talien Wan to Japan. She was disinfected no less than four times. This vessel used sand for ballast, and this ballast was not changed during the epidemic. The sand was picked up in India somewhere, just before the beginning of the war, and Dr. Arnold thinks that it had something to do with fostering the disease. He will make a thorough investigation of this vessel's history.

Provision Made in Minnesota for Expenses in Controlling Epidemics

—The law of Minnesota relating to the control of infectious diseases was amended in 1895 so that it shall be the duty of the chairman of any town, village, or city board of health which has incurred expenses for the control of infectious or contagious diseases in any such town, village or city to file an itemized statement thereof duly verified, under oath, with the clerk or recorder of such town, village or city, and thereupon it shall be the duty of the town supervisors, or the council of any city or village to audit and pay the said statement, or so much thereof as they deem just and proper, in the same manner as other accounts against such town, village or city are audited and paid. For this purpose, towns, villages and cities are authorized to levy an additional tax, not to exceed one mill of the dollar, of taxable property in any one year. But this enactment is not to apply to any city where provision was already made by law for the payment of such expenses by said city.

Tubercle Bacilli in Milk and Meat.—This subject is strongly handled by Dr. Simonton in an article in the *San José Mercury* of January 18. He calls attention to the fearful statistics of the death rate from tuberculosis in this country and says that as it is a preventable disease it should be terminated. Persons already afflicted should not be allowed to infect others with their sputa drying on sidewalk and step, and whole herds of cattle should be swept out of existence if necessary. He asserts that most of the 18,000,000 gallons of milk used here annually contain germs of tuberculosis, and that 15 per cent. of the cattle in California are already infected. He then makes a vigorous appeal to have the meat inspector and health officers generally, paid a generous salary, in proportion to the vital importance of their task, so that they could act without fear or favor, promptly and energetically. It is "a serious

matter to go into a man's dairy and kill his cattle," especially if he is a friend and patron of the official. The office should be dignified and remunerated until friendship and patronage are considered trifles in comparison with the disease and death the dairyman is scattering broadcast.

Precautions about Sending Tuberculous Patients Away from Home.—One of our religious journals contains an interesting and timely bit of correspondence that goes to show what may often occur when consumptives are sent to certain parts of the partially developed South, without the proper financial provision. Patients are not infrequently sent away, or allowed to go South without funds sufficient for their maintenance while away from home. Some patients are said to go in the expectation that they will be able to get work, when oftentimes there is no work suitable for them to do, and they may be without the strength to do it, even if it is to be found. The inference is inevitable that this "getting of work" for the patient should not be left to a chance, but should be looked into carefully before the journey is undertaken, unless the financial provision is so ample that the patient may not be overtaken by privations if the work is not procurable.

A clergyman in El Paso, Texas, writes to *The Evangelist* asking charitable friends to be careful in sending people there for treatment of pulmonary troubles, to make sure that they have enough to support them while there. The different churches are by no means strong, and find themselves very heavily taxed to support the very many needy invalids sent from other places. Such sick poor, he says, are "unloaded on us every winter by the score." They are expected to find work, but there is no work for them save in very exceptional cases. While disclaiming any desire to be harsh or uncharitable, he says: "If their friends can not support them here, we beg of them not to send them. Keep them at home that they may die of consumption among friends, and not of consumption, plus starvation, among strangers."

Legislation to Protect Health in Minnesota.—Several laws were passed in 1895 by the legislature of Minnesota designed for the protection of the public health. One of them, chapter 199 of general laws, provides for the sanitary regulation of bakeries and other establishments for the manufacture of bread and other food products. It prescribes how buildings therefor are to be constructed. No water closet, earth closet, or privy or ash pit shall be within or communicate directly with the bake room or any other room used in the manufacture of bread or other flour or meal food products, and the sleeping places for workmen shall also be separate and distinct therefrom. Ample toilet facilities apart from the utensils used in the preparation of food are to be furnished, as well as caps, slippers or shoes and an external suit of coarse linen. Furthermore, no person shall work or be employed in or about any bakery or other establishment for the manufacture of food products during the time in which a case of infectious disease exists in the house in which he resides nor thereafter until the local board of health issues a certificate in writing that no danger of public contagion would result from the employment of said person in said establishment. It is made the duty of the state bureau of labor and the boards of health, state and local, to see that the provisions of this act are enforced, while in cities of over 5,000 inhabitants, the common councils may require the owners or managers of such establishments to take out licenses. Chapter 200 requires all dealers, whether wholesale or retail, and others, in slaughtered fresh meats of all kinds, or in fish, fowls or game for human food, or for family use, to protect the same from dust, flies and all other obnoxious, offensive and deleterious insects, vermin or substances, while being transferred from place to place, to their customers, by securely and properly covering same with protectors, either tarpaulins, sheets or other effective covers. Chapter 201 aims to suppress the sale at

retail of decayed, tainted and unwholesome plucked poultry and game, particularly by requiring the entrails, crops and all other objectionable and offensive parts removed therefrom. Chapter 202 requires receivers of milk or cream in cans, bottles or vessels, shipped by rail or boat, which are to be returned, to empty same before the contents sour and to immediately wash and air the cans, etc. Chapter 203 relates to the inspection of milk and of dairies and of dairy herds. Chapter 204 is to prevent the adulteration of candy.

A More Aggressive Campaign Against Tuberculosis in New York.—On January 18, the New York City Board of Health made public a report of Dr. Herman M. Biggs, pathologist, and Dr. T. Mitchell Prudden, consulting pathologist of the Health Department, on the subject of expectoration in public buildings and conveyances. Circulars of information have already been published and distributed by the department, and some bacterial diagnostic work has been done by the Bureau under the charge of Dr. Biggs; but the officials feel that the time has come to make another advance. They will recommend that notices be posted in all public places and in all surface and elevated cars in this city, signed by the Board of Health, warning passengers against expectoration upon the floor of those conveyances; and further that similar notices be posted in the stations of the elevated roads, warning people against expectoration upon the platforms and stairs, or on the floors of the stations. The report above referred to says: "It has been for a long time known that the expectoration of persons suffering from laryngeal or pulmonary tuberculosis, pneumonia, influenza or the grip, and from diphtheria, contains the specific germs of these different diseases, and is capable of inducing these diseases in others. There is, furthermore, much evidence that a similar condition exists in certain more readily communicable diseases, such as scarlet fever, measles and whooping cough. In regard to some of these affections, the danger from the expectoration in public places is of course small, as the patients are ordinarily confined to their homes during the infectious period. But this is not universally the case. It has long since been shown that the chief means for the transmission of consumption is the dried and pulverized sputum of persons suffering from the disease. These germs are liable to be gathered on the feet and on the skirts of women, and taken into private houses, where the most perfect ventilation will not stay their evil effect. Expectoration in public places should be abated, as any other public nuisance which is brought to the attention of this department. That it is a habit and not a necessity, is clearly enough shown by the large number of men who are free from it, and the insignificant portion of women who practise it. There seems to be no good reason for the longer sufferance by the mass of people of the carelessness and the negligence of the few. We believe that this is a matter of great importance, and that on this ground alone it demands the interference of your Board. We believe that the time has now arrived when the people of the city of New York will heartily support the adoption of such sanitary measures as may seem necessary and expedient for the abatement of this widespread nuisance and source of danger."

The "Sacred Breath Cube" for Factories. Ventilating Fans in Laundries.—The *Medical Press and Circular*, January 8, states that a new law as to factories went into operation in Great Britain, at the beginning of the year 1896. The cubical air-space is, by the new act, moderately increased, but can not be said to be extravagantly high, but from a general sanitary standpoint the *Press* concludes that "the new measure constitutes a considerable advance upon all previous enactments of a similar nature. First and foremost the great principle of the prevention of overcrowding in work places has at length been formally recognized by the legislature of this country. The Act provides that a factory or workshop shall be deemed over-

crowded, so as to be injurious to the health of its inmates, if there be less than 250 cubic feet of space to each person during overtime. At the same time, there is an important rider to the effect that the Secretary of State may modify this proportion for any period during which other than electric light is used, and may as regards any particular manufacturing process or handicraft substitute any higher cubical figures than those mentioned. The necessity for such a proviso in many trades—such as baking—will be at once evident to all who are familiar with industrial processes. Then we find that the powers of the administrative authorities are greatly increased. Thus, a court of summary jurisdiction, meaning in London a police court, may on complaint by an inspector, and on being satisfied that a factory or workshop is in a dangerous or insanitary condition, prohibit the place from being used until such works as are necessary to remove the danger have been executed. This provision will strengthen the hand of the factory inspector to an almost incalculable extent. Adequate penalties are provided for the employment of persons in places injurious to health, or for allowing wearing apparel to be made up, cleaned or repaired in places where there is scarlet fever or smallpox. The last clause is so directly practical, so obvious, and so elementary as a common-sense first step in prevention or the spread of infectious disease, that the only wonder is why it was not placed on the statute book a generation ago. Further important provisions are made in the case of death from accident in a factory or workshop. Notice of occurrences must be given and a full register of them kept by the owner or occupier. A factory inspector must also attend the subsequent inquest, and the Home Secretary is furnished with powers for additional investigation should he think fit. Another most salutary feature of the new bill is that laundries carried on by way of trade, or for purpose of gain, are brought under the control of the Factory Act. In steam laundries fans must be provided to regulate the temperature of ironing rooms and to carry off the steam of wash-houses: stoves are to be separated from workrooms: the use of gas-irons emitting noxious fumes is forbidden: and floors are to be kept in good condition and properly drained. These improved conditions can not fail to confer an immense boon upon a hitherto neglected and oppressed class of workwomen. At the same time it is not a little curious that women engaged in this laborious and unhealthy trade are allowed to be employed for excessive hours of labor. A number of provisions are made with a view to enforcing the duties of employers in the observance of sanitation, of the fencing of machinery, of the affixing of notices, and of the general carrying out of their responsibilities under the Act. In the case of tenement factories we note the practical point that the owner is made responsible in place of the occupier, who is often a man of straw."

The new law is manifestly a step in the right direction and constitutes a notable landmark in the history of factory legislation.

Health Reports. The following health reports have been received in the office of the Supervising Surgeon General Marine-Hospital Service:

SMALLPOX—UNITED STATES.

Louisiana: New Orleans, Jan. 11 to 18, 3 cases, 1 death.
Michigan: Detroit, January 11 to 18, smallpox reported.
Missouri: St. Louis, January 21, 1 case.
Tennessee: Memphis, January 18 to 25, 2 cases.

SMALLPOX—FOREIGN.

Dublin, January 4 to 11, 3 cases.
Glasgow, December 28 to January 4, 3 cases.
London, January 4 to 11, 3 deaths.
Madrid, January 1 to 7, 10 deaths.
Montevideo, December 11 to 21, 1 case.
Nogales, January 11 to 18, 2 cases.
Odessa, December 28 to January 4, 4 cases, 2 deaths.
Rotterdam, January 4 to 11, 2 cases.
Swansea, January 4 to 11, 1 case.
Tuxpan, December 21 to January 4, 2 deaths.
Warsaw, December 21 to January 4, 3 deaths.

CHOLERA—FOREIGN.

Bombay, December 17 to 24, 1 death.
Calcutta, December 7 to 14, 42 deaths.

YELLOW FEVER—FOREIGN.

Havana, January 9 to 16, 5 cases, 2 deaths.
Cienfuegos, January 5 to 19, 2 deaths.
Santiago, January 11 to 18, 6 deaths.
Sagua la Grande, January 4 to 11, 5 cases, 1 death.

BOOK NOTICES.

Miskel, A Novel. By L. M. PHILLIPS. M.D. Franklin, Ohio: The Editor Publishing Co.: New York: Bailey, Fairchild & Co. 16mo, cl., pp. 266. 1895. Price 50 cents.

This is number 2 of the Doctor's Stories, a series of "medical" novels which we are informed will hereafter appear with regularity. The story turns largely upon hypnotism and Hindoo magic. A baby is stolen in Lucknow; the father, an English officer, also abducted. In course of time the custodian of the child becomes a resident of an Ohio town, where she astonishes the good people of that slow but altogether correct village by her wealth, her beauty, her accomplishments and her magic, and knowledge of the hypnotic art. She finally hypnotizes and ruins the only bank cashier, and runs a career of astonishing riot which finally takes her East to consult Hammond, Ranney and other neurologic luminaries: but through the doubly diabolic agency of her two Indian servants, who feed her on hasheesh, the prognostications come to naught and she seeks refuge in an inebriate asylum, only to die by the knife of one of the Hindoo assassins. Meanwhile by phenomenal valor, and the courage and ability of a self-sacrificing friend, the officer is restored to his family and everybody is happy forever afterward. On the whole it is a clever story.

Food Products of the World. By MARY E. GREEN, M.D. Edited and Illustrated by GRACE GREEN BOHN. Chicago: The Hotel World. 16mo, cl., pp. 248. 1895.

We can not have too many books on this subject, so long as man must be fed and depends upon food products for his supply. When the time comes that we shall be fed by some new and savory synthetic compound so highly concentrated that only a few drops will suffice for our daily nourishment, perhaps the study of food may lose its interest for us; but then as there will be no need for a digestive apparatus, it must be more or less speculative, regarding the particular mental pabulum that may interest the coming chemic race. Be that as it may, "while we live, let us live," and Dr. Green's book will be found a mine of information on foods. But the mine is intrinsically attractive, and one is apt to linger long over its developments.

The vast information possessed by the authoress is so charmingly placed at our disposal in this little book, that the literary as well as the gastronomic gourmet must be satisfied.

"The subject matter in this book," says the preface, "was originally published in a series of magazine articles begun just after the close of the World's Columbian Exposition. The fact that at the Exposition was gathered the most complete and cosmopolitan array of food products ever displayed, is sufficient apology for the frequent allusions made to these exhibits throughout the book." The hygienic and nutrient values of foods are well and clearly stated, and we have no hesitation in placing this at the head of recent works on foods. Its style is agreeable and there are few instructive works that can be read with more pleasure. The authoress is patriotic to a degree, and the great Exposition is a prolific theme. Hear her:

"Nothing equaling the agricultural displays of our States and Territories was ever seen before. The wheat lands of Canada and our own great West sent their contribution in cereals of superior quality and statistics of immense production. Corn was there in all its glory of waving leaf and tassel as decoration upon the booths, and in its richness of yellow and white, as the exhibit proper. The fruit belts of California, of our Middle States, of the South and East were

represented by such displays as would have graced the banquet-board of an Epicurus. Apples, pears, plums of royal purple and gold were there, grapes worthy to crown the temples of a Bacchus, and oranges from the west and south, the golden apples of our own Hesperides."

Addresses, Papers and Discussions in the Section on Surgery and Anatomy at the Forty-sixth Annual Meeting of the AMERICAN MEDICAL ASSOCIATION, held at Baltimore, Md., May 7-10, 1895. Chicago: AMERICAN MEDICAL ASSOCIATION PRESS. 1895. Price \$1.

This Section book of the ASSOCIATION contains the work of the last Section meeting, and it is regretted that owing to the failure of the stenographer who had been engaged for reporting the discussions, no discussions in these Sections were available. The stenographer was engaged on recommendation of some of our well known members, and it was not known until after the meeting that he was wholly incompetent, too late to remedy the error. Therefore the papers have been published as delivered without the discussions. There are several among them that will be of permanent value to surgical literature. The contributors to the volume include the names of Howard A. Kelly, W. K. Otis, F. C. Valentine, John B. Deaver, Nicholas Senn, John B. Roberts, Christian Fenger, E. B. Davis, J. McFadden Gaston, De Forrest Willard, J. B. Murphy, W. B. De Garma, Henry O. Marcy, B. Merrill Ricketts and others. The chairman, Dr. Jos. Ransohoff, is to be congratulated on the excellence of the program, and the general appearance of the volume.

NECROLOGY.

JAMES A. BLANCHARD, M.D., of Brooklyn, who for fifteen years was superintendent of the Inebriates' Home, died suddenly January 8, at the institution where his duties had kept him in a position of more or less professional isolation, ever since 1881. Dr. Blanchard was born in Norwich, Conn., fifty-five years ago, and studied in the schools of his native town until 1858, when he settled in Brooklyn and took up the study of medicine and surgery at the College of Physicians and Surgeons, in New York, from which he graduated in 1867. He then practiced his profession in this city until 1878, and in that year received the appointment of assistant superintendent of the Kings County asylum for the insane at Flatbush. His success, while in private practice in the treatment of mental diseases, was followed by a similar success in the management of the insane poor: and in 1881 he was made superintendent of the Inebriates' Home at Fort Hamilton, a position which he held until the year of his death. He was during nearly all these years, handicapped in being connected with this semi-political retreat, against which from time to time there would be a clamor for investigation, but against which the better class of citizens have in vain protested. Special legislation, even, has seemed powerless to effect any reform. During the war of the Rebellion, Dr. Blanchard enlisted in the Twenty-third New York Volunteers, and for valuable services rendered was promoted to the medical corps. At the end of a year he was obliged to leave the service on account of ill health and coming home resumed his medical studies. He belonged to the Hamilton and Crescent Clubs of this city, the Twilight Club of New York, the Kings County Medical Society and the Physician's Mutual Aid Society. His wife and one daughter survive him. The cause of his death was an attack of pneumonia, of two weeks' duration, culminating in cardiac syncope.

KENNETH N. FENWICK, M.D., of Kingston, Ontario, died January 21, in consequence of pyemia following an operation done a few days before on an eight-year-old child. He was professor of the Institutes of Medicine at the Royal College of Physicians and Surgeons, and a member of the attending staff at the General Hospital at Kingston. He was an ex-vice-president of the Ontario Medical Association. In addition to his

medical degrees of Canadian origin, he was a member of the Royal College of Surgeons of England.

F. R. DYER, M.D., of Ottawa, Ill., January 25, aged 43.—Albert Dart, M.D., Goshen, Ohio, January 15, aged 94.—H. N. Mackey, M.D., of Morgantown, W. Va., January 21, aged 67.—Benjamin Cory, M.D., of San Jose, Cal., January 16, aged 74.—W. D. Morehouse, M.D., of Wauwautosa, Wis., January 17, aged 64.—M. A. MacOwen, M.D., of Utica, N. Y., January 19, aged 76.—A. W. Lozier, M.D., of New York, January 14.

MISCELLANY.

Access to College Laboratories.—The members of the Académie de Médecine have placed on record their unanimous desire that every medical school and college should have a special experimental laboratory for the study of bacteriology, accessible to all the physicians and druggists of the place.

Serum by the Quart.—A Bordeaux physician has recently vaccinated some cases of variola with serum from a vaccinated young cow, injected hypodermically in quantities varying from one-twentieth to one-fiftieth of the weight of the patient. These large quantities produced no inconvenience, but were followed by immediate recovery. One and one-half liters were injected in the course of an hour in one case. —*Sem. Méd.*, Jan. 15, 1896.

Tuberculosis in a Penal Institution.—The Charities' Board of Kings County, New York, have voted to fit up a separate ward in the hospital attached to the Kings County Penitentiary for the reception of patients suffering from consumption and pulmonary diseases. The new ward will be located where the ironing and drying room used to be. It was lately moved into the laundry building. This improvement is made upon the recommendation of the physician attached to the penitentiary. There are at present twelve convicts whose condition makes it expedient to remove them to such a ward.

Authorizes Incorporation of Medical Societies.—A law was passed in the State of Washington in 1895 which provides for the incorporation, by two or more persons within that State, of associations for the prosecution of scientific or medical purposes. Such corporations can make their own by-laws, hold real and personal estate, hire or erect buildings for their own accommodation, and may receive and hold in trust, or otherwise, funds received by gift or bequest, to be devoted to the purposes for which they are organized. Preëxisting societies can come under the provisions of the law, if they desire to do so.

The International Scientific Language. The *Archives Cliniques de Bordeaux*, December, 1895, has a complimentary notice of Dr. Hamilton's address to the American medical editors on this subject. We translate a few lines: "It always reminds us of that incident in Grecian history when the generals were to elect a commander-in-chief, and each man voted for himself in the first place, but the second choice was unanimously in favor of Themistocles. Each man wants his own mother tongue to be adopted for the international scientific language, but the second choice is invariably in favor of French. Dr. Hamilton, however, is so liberal as to place French in the first place, which is remarkable, coming from an American." It concludes by endorsing all his remarks in regard to Greek, Latin and other languages.

William H. Thorndike Prize Fund. Mr. Townsend W. Thorndike has given \$5,000 to the Harvard Medical School to found the William H. Thorndike Prize Fund in memory of his father. From the interest of this fund a prize of \$200 is to be given annually to the author of the best essay on some subject in any branch of surgery. The students of the Harvard Medical School and graduates of under five years' standing of any recognized medical school shall be eligible in competition for it.

According to the wishes of the donor, should the principal increase to such an amount as should be considered sufficient to warrant the offering of a second prize of lesser amount from the interest of the fund, such a second prize is to be established, to be known also as the William H. Thorndike Prize. — *Boston Med. and Surg. Jour.*

A Bit of Pseudo-science, or the Early Photographic Diagnosis of Variola. The following amazing paragraph is taken from an American journal that covets the name of being a teacher of science. The writer has evidently forgotten to ascertain what is the length of the incubative period of variola:

"A Manchester photographer relates that he recently took a photograph of a child who was apparently in good health and had a clear skin. The negative showed the face to be thickly covered with an eruption. Three days afterward the child was covered with spots due to prickly heat. The camera had seen and photographed the eruption three days before it was visible to the naked eye. It is said that another case of a similar kind is recorded, where a child showed spots on his portrait which were invisible on his face a fortnight previous to an attack of smallpox."

The Return of the African Explorer, Dr. Donaldson Smith. The December 20 issue of the *Science* contains the following news item: "Dr. Donaldson Smith, who left England in the summer of 1893, with the object of exploring Lakes Rudolph and Stephanie, has just reached England. Since February, 1894, nothing had been heard of him, until a telegram from Aden, at the beginning of November, announced the success of the expedition, and the arrival of Dr. Smith at that place. Dr. Smith will read a paper before the Royal Geographical Society next month, and in January will return to America, where an account of his travels will be published." Dr. Smith is, we are informed, a Philadelphian by birth, and a graduate from the University of Pennsylvania about six years ago. The lakes above mentioned are in an almost unknown territory, lying northeast from the Victoria Nyanza, in Eastern Equatorial Africa.

Lupus of the Tongue. The tongue is neglected by the specialists: it does not belong to dermatology nor to laryngology, and consequently has little or no literature of its own. Lupus of the tongue is extremely rare, and an indolent trouble that is scarcely noticed. Nearly every case noted was discovered while an examination was being made for some neighboring affection. Dr. Spire sums up all the known cases on record, fourteen in all, from Bazin and Virchow in the sixties to his own experience, in an article in the *Archives Cliniques de Bordeaux*, December, 1894. In every case there were similar lesions on neighboring organs, and the lupus had the same appearance in all. In treating the case the characteristic nodule must first be destroyed. Dr. Moure paints it with phenic glycerin. Leloir applies a salicylized paste: Volkmann's curette may bring on a hemorrhage: Michelson used successfully a galvanocauterizing bath, but of all methods the author advocates ignipuncture, as being harmless, rapid, not painful after the part is treated with cocaine, and very satisfactory in its results.

Infective Stomach Hemorrhages of Angiocholitic Origin. Dr. Rondot's paper read before the French Congress of Medicine, August, 1895, and given at length in the *Archives Cliniques de Bordeaux*, December, 1895, is an interesting study of two unusual cases of hemorrhage of the stomach, from which he concludes that suppurative inflammations of the biliary ducts, such as an areolar abscess of angiocholitic origin or suppurative cholecystitis, may be accompanied by hematomesis with pain, thus simulating the symptoms of simple ulcer of the stomach. These gastric hemorrhages may appear in the course of biliary affections which manifest their presence by fever, enlarged spleen and the phenomenon of endocarditis and myocarditis. They seem to progress by feverish rushes, with pains foreign to the disease known as Cruveilhier's. These may be

followed by periods of deceptive calm, during which the latent trouble reveals itself by symptoms of endocarditis and hypertrophy of the spleen. The persistence of the cause explains the return and the dangers of the different symptoms. If they do not produce death directly, they may give place to symptoms of an infection with every phenomenon of infective endocarditis with hyperthermia and rapid degeneration of the muscles of the heart.

Reciprocal Medical Registration Lacking in the Dominion of Canada. The *Montreal Medical Journal*, in its report of the proceedings of the last meeting of the Canadian Medical Association, emphasizes the fact that there is still wanting in the Dominion an equitable and fair intercolonial medical registry. The *Journal* points out the desirability of an early settlement of this question, for it almost prejudices every application that is made to the British General Medical Council for a reciprocal registration with the mother country. There is so much at stake, the *Journal* thinks, that the matter should be pressed forward to its issue. The *Journal* further says:

The committee appointed at the last meeting of the Association to look into the question of inter-provincial registration expressed their regret that by the system which at present obtains, a graduate of medicine entitled to practice in one Province is not free to exercise his functions in all the Provinces in this large but sparsely settled Dominion, that this condition of things prevents the names of medical practitioners in this Dominion being placed on the British register, becoming thereby British practitioners. This latter is a boon which the council of Great Britain has more than once signified its willingness to grant. To secure these ends it is considered most desirable that a uniform standard of medical education for the whole Dominion be established. In order to effect this purpose it is suggested that the Secretary be instructed to communicate with the various provincial councils before the next meeting, asking that each council discuss the position and if possible appoint one or more delegates to a Dominion committee for the purpose of adjusting a suitable curriculum to carry out the suggestions herein, and that such committee be requested to forward its findings to the secretary of the association before the next meeting.

Somatic Illumination by Electricity. An Electrical Oscillator.—Two electrical discoverers report about simultaneously new medical and surgical uses for an extremely powerful electrical light. One of these, the claimed surgical application of such light, has been made by Rontgen, of Würzburg. The following condensed statement on this subject is taken from the *Medical Press and Circular* for January 8:

"The news of a remarkable discovery in photography is reported from Vienna. Briefly, it consists in the discovery of a new conductor of light. Professor Rontgen, the well-known professor of Würzburg University, has succeeded in photographing metal weights shut up in a wooden box, without showing anything of the casing on his negative. He is also said to have photographed the bones of the hand, all the soft parts being invisible. He photographs by means of light of an exhausted Crookes' tube through which an inductive current is passed. The discovery appears to be so far that the rays in question penetrate wood and flesh, but not bone or metal. It is surmised that photographs of the kind mentioned may have a valuable practical application in the discovery and location both of fractures and of bullets. If this discovery be sustained it will certainly take a first place among the many marvels of this scientific age. Those of our readers who are versed in electrical research may have already heard of Professor Rontgen's interesting researches."

A second claim, that of the American electrician Nicola Tesla, is laid that a strong electrical light can be developed powerful enough to penetrate the body-tissues and destroy certain pathogenic bacilli. He believes that he has produced an artificial light which, under certain conditions, is powerful enough to penetrate the human integuments. The last named was taken up some months ago by a physician in Vienna, who

it is alleged has discovered that by its use the bacilli of tuberculosis may be destroyed. By its means the most remarkable medical cures may become possible.

Another discovery by Tesla is that of an electrical oscillating machine for localized treatments and for general passive exercise. In an interview with a New York *Herald* reporter, Tesla gives the following explanation:

"The oscillator is a platform, which produces a number of more or less violent mechanical vibrations. For persons whose systems are in need of exercise this is said to be particularly useful. Force of movement can be given to the oscillator equal to the exercise or shaking up of the system which could be obtained by walking or riding for half an hour or even an entire day. These results are obtained without the fatigue which would result were the exercise taken in customary ways. These conditions are brought about through the use of electricity, powerful but minute electric shocks being rapidly distributed through the system.

"Mr. Tesla intends making several oscillating machines and placing them in the hands of certain physicians or medical institutions for the purpose of having their usefulness positively determined."

The Pithecanthropus Erectus.—In *Science* for December 20, Dr. D. G. Brinton gives his editorial review of the newest facts regarding the prehistoric man from Java. This remarkable find of the Dutch surgeon, Dr. Dubois, of a creature considered by him to be intermediate between man and the apes, has been the subject of wide discussion during the past year. Dr. Brinton says:

"So many have been the articles for and against the accuracy of his statements and conclusions, that the Dutch government sent for him to come in person and bring all his specimens to the International Zoological Congress in Leyden, in October last. He punctually appeared, with a large number of mammalian bones from the formation in which the *Pithecanthropus* was found, and an additional tooth of the animal itself. The geological experts present decided that the various bones indicated the oldest pleistocene or else the youngest pliocene. The anatomists expressed themselves about the skull, teeth and femur of the alleged 'missing link.' Professor Virchow, probably the most conservative, maintained that the bones were of an ape; but an ape generically distinct from any known; and if the skull and femur belonged to the same individual, then it was an erect ape, walking like a man; but he would not acknowledge that it bridged the gap between the anthropus and the anthropoid. Practically the same result was reached by the eminent French anatomist, Dr. Manouvrier. He studied the originals in the possession of Dr. Dubois; and he declares there can be no doubt that in them we see the remains of a creature intermediate between man and the ape, walking erect, with a cranium like that of the gibbons, but much larger than any existing gibbon. The conclusion is indisputable that in the *Pithecanthropus* we have an animal higher than the highest ape and lower than the lowest man."

A Defense of Doctor Jameson.—The *British Medical Journal* of January 11 contains the following defense of Dr. Jameson, whose operations in South Africa have been the subject of much comment:

"Nothing in the present crisis is more remarkable than that, through the general voice of national lamentation that has gone up about this miserable business in the Transvaal, the note of personal regard and even admiration for the man who has been the leader in it has made itself loudly heard. Hard things are being said of others; of Dr. Jameson the bulk of his countrymen simply refuse to believe that his misguided action was prompted by any other thought than the wish to save those whom he deemed it his duty at all risks to rescue from what he considered to be a position of imminent and deadly peril. This tenderness for a man who in the eye of international law is a freebooter, and who has committed the kind of mistake which Napoleon described as worse than a crime, will easily be understood by those who knew him before he had any thought of forsaking the peaceful career of medicine to follow in the footsteps of Cortes and Pizarro. As several more or less inaccurate accounts of Dr. Jameson's early career have appeared in the general press, the following particulars may not be without interest: He is now just 43 years of age. Though Scotch by birth, as far as his medical education is concerned he belongs wholly to University College. He entered that school in 1870, became a member of the Royal College of Surgeons in 1875,

and graduated as M.B. and B.S. in the University of London in the same year. He took the degree of Doctor of Medicine in 1877. His career as a student was a distinguished one, and he held the posts of house surgeon under the late Prof. John Marshall, and of house physician under Sir Russell Reynolds. He was afterward appointed resident medical officer to University College Hospital, but his period of office was interrupted by a voyage of some months to the United States, where he went in charge of a patient, and was cut short by the fact of a good opening for practice presenting itself at Kimberley. As an example of his energy of character it may be mentioned that within a day or two of the offer reaching him he began to prepare himself for his new life by taking riding lessons at the Albany Street Barracks. His subsequent career is known to all men. As a young man Dr. Jameson gave evidence of the same personal magnetism which has so endeared him to all sorts and conditions of men. To his intimates among his fellow students he was 'Jimmy' as he is now 'Dr. Jim' all over South Africa. He was a man of the most generous instincts. If impulsive, there was nothing ignoble about him. There was no taint of selfishness in his nature, and he was simply incapable of meanness or deceit. No one who knew Jameson, as men know each other in the unrestrained intimacy of fellow studentship, could for a moment believe that he would consciously have lent himself to any act of treachery or disloyalty. His professional brethren are still proud of him, and assuredly will not condemn him unheard."

Practical Notes.

Abscess Following Injections of Benzoate of Caffein. The *Sem. Méd.*, Jan. 15, 1896, records a case of pneumonia treated with subcutaneous injections of benzoate of caffein, where abscesses followed at the spots where the injections had been made. The pus of the abscesses contained pneumococci in a pure state.

Rectal Medication. Dr. Mastboom, of The Hague urges the profession to pay more attention to this form of medication and thus lift some of the burdens from the stomach. He has obtained exceptionally fine results with salicylate of soda in cases of grippe and rheumatism, as also with creosote, antipyrin, bromids, iodids and arsenic. He uses small doses, not more than 15 gr., well diluted and warmed.

Bronchitis and Pneumonia Produced by Ether. Anesthesia by means of ether is still vigorously combatted by some physicians. Among them Mickulicz, who noted three cases of asphyxiation in eighty cases where it was used. But Grossmann has observed 250 cases at Dr. Landau's clinic in Berlin, without a single complication, and he writes to the *Deutsch. med. Woch.*, No. 29, 1895, to call attention to Landau's method of placing the head of the patient in such a way, with the corner of the mouth open, that the mucous and saliva run out of themselves, and are not drawn in with the breath to produce strangulation or those rhonchi which give rise to the suspicion of lung or bronchial inflammation. *Rev. Internat.*, Jan. 10, 1896.

Treatment of Chronic Endometritis by Cauterization with Steam. This method of hemostasis suggested by Professor Sneguirev of Moscow, a year or so ago, has been successfully employed by Dr. Panecki, of Dantzie, in intra-uterine cauterizations, which are described at length in the *Semaine Médicale* of January 15, 1896. He uses a simple heater supplied with a thermometer. It fits over an alcohol lamp which boils the water. The steam is introduced into the vagina through a rubber tube and catheter, when the thermometer shows a temperature of 100 or 120 degrees for severe cases. As the lining becomes cauterized the parts near the opening turn white, and drops of a reddish liquid fall from the vagina. When about a teaspoonful of this liquid has accumulated, the lamp is extinguished, and a tampon of medicated gauze inserted. The operation does not require an assistant. It should be repeated at intervals of eight to ten days. It affords immediate relief in cases of catarrhal endometritis and is followed by marked improvement in this usually obstinate trouble, which differs from fungous hemorrhagiparous endometritis by its hypersecretion without menorrhagia.

Syphilis of Epiglottis. At a recent meeting of the Berlin Medical Association, Dr. Hansemann described a new syphilitic symptom hitherto not recognized as such, although it is of frequent occurrence. It is an inflammatory condition of the epiglottis, commencing at the extreme root of the tongue and working outward. The inflammation causes retraction of the epiglottis, which in time becomes anteflexed and even doubled. In the autopsy of fifty-five cases with unmistakable indications, Dr. H. noted twenty-five with the epiglottis anteflexed, thirteen shriveled and seventeen normal. In five cases the epiglottis was anteflexed without any other indications of syphilis, although atrophy of the root of the tongue was present in one case. As it is not infrequently important, to be able to determine definitely the presence of constitutional syphilis at an autopsy, this condition of the epiglottis may well support the suspicion of syphilis.

Treatment of Diabetes. At the same meeting Dr. Hirshfeld made a plea for individual treatment of cases of diabetes, as many intercurrent disorders cause the secretion of sugar to increase or diminish and different patients are affected differently by the same drugs as he explained in detail. The secretion of sugar diminishes in all patients with the withdrawal of carbohydrates, but this effect occurs very soon in some and tardily in others. This diminished glycosuria is not, however, an improvement in the disease, as many patients have serious troubles, especially coma, even with a longer continued and almost exclusive meat diet. The beneficial result of this diet seems to be a partial inanition because the consumption of the tissues is not covered. This deficient nutrition, as well as a too abundant diet, affect patients differently. Dr. Hirshfeld does not distinguish between curable and incurable diabetes, but considers them all phases of one disease. — *Deutsche Med. Wochens.*

Fever as a Factor in the Evolution of an Infective Disease.—At a recent meeting of the Académie des Sciences, M. Cheinisse described some experiments he had been making to determine the exact rôle played by the fever in the evolution of an acute disease. He selected infection from staphylococci, as the disease most easily studied and followed. His experiments were suggested by observing the effect of painting the skin with guaiacum, the new method of lowering the temperature. He found by his experiments that the suppression of the fever produced by painting with guaiacum, causes the disease to assume a virulent form. It resulted in the death of the animals thus painted, in twenty-four to forty-eight hours, from virulent septicemia, forestalling the formation of lesions. In the animals infected without further treatment the disease progressed to a fatal termination in two to four weeks, resulting in multiple abscesses in the kidneys, liver and heart (general purulent infection). He is convinced that this result obtained by painting animals affected with fever with the guaiacum is certainly due to the lowering of the temperature, and not to the act of painting, nor to any toxic action of the guaiacum. — *Sem. Méd.* Jan. 15, 1896.

Serotherapeutics of Tuberculosis. Since the Tuberculosis Congress of 1893, Messrs. Babes and Proca, who read a paper there, have been experimenting with dogs, sheep and asses, inoculating them with tuberculin and also with dead bacilli that have served in the production of tuberculin, as they found this combination more effective. They found that tuberculin would cure tuberculosis under certain conditions, if treatment was commenced very soon after infection. But it could be cured with much greater certainty by injections of serum commenced several days after infection and repeated several times, especially if serum used is taken from animals that have been treated with both tuberculin and dead bacilli. The latter after being removed from the tuberculin and after having passed through the body of the animal seem still to retain a

certain active principle which, without producing the fever characteristic of tuberculosis, still reproduces the local lesions similar to the pathologic products of the live bacilli. The accounts of their innumerable experiments was presented to the Académie des Sciences at the meeting of January 6, and is reviewed at some length in the *Semaine Médicale*, Jan. 15, 1896. One fact they insist upon is that the doses of serum must be comparatively large. Small doses are insufficient and only aggravate the disease.

Diphtheria Sine Antitoxin.—In the *New York Medical Journal* Dr. O. B. Douglas, a specialist of note in that city, writes that he is among those who have not yet been converted to the new remedy. He advocates local treatment, as well as a faithful and moderate medication. He says: "In treating diphtheria and all acute inflammations of the throat, mild medicines given often will serve you far better than harsh and heroic treatment at long intervals. I do not believe that antitoxin has come to stay. I know of no surer way to cure diphtheria than to attack it *in situ*. My method which has given best results is to begin at the earliest stage possible, and give the following medicines with unflinching regularity:

No. 1.

R Tinct. aconiti.	gtt. xx	1/20
Tinct. belladonnae.	3 ss	2/00
Glycerini.	3 iv	16/00
Aquæ gaultheriæ.	3 iv	120/00

No. 2.

R Potoss. chloratis.	aa	3 ss	2
Sodii bromidi	3 ss	15	
Glycerini	3 ss	2	
Tinct. ferri chlo.	3 iv	120	
Aquæ.	ad	3 iv	120

Dose: Half a teaspoonful for an adult.

These are to be given alternately every half hour, thus bringing the doses fifteen minutes apart. This frequency may seem severe upon the patient who gets little sleep during the first twenty-four hours, but we have a severe antagonist to combat and must not relax our warfare until we conquer, which I expect to do with almost as much certainty as I should in a case of measles. In addition to Nos. 1 and 2, I should always use a spray, often and freely, composed of twelve grains of carbolic acid in four ounces of lime water. All these preparations are agreeable to take. I give liquid nourishment freely, milk being ordinarily best; also whisky, sparingly at first, but sufficiently to get the desired effect as a tonic. Bichlorid of mercury may be of service sometimes. Intubation or tracheotomy is to be resorted to if necessary.

Hospital Notes.

MINNESOTA'S FOURTH HOSPITAL FOR THE INSANE.—In 1894 a law was passed in Minnesota creating a commission to locate, acquire land and prepare plans for a fourth hospital for the insane. Among the requirements was that it should be as near as possible to the cities of St. Paul and Minneapolis. Provision was also to be made for a separate ward for insane criminals. And the commission was to consider and report upon the advisability of adopting the cottage plan and methods for this institution.

THE ANNUAL REPORT of the Baltimore Presbyterian Eye and Ear Hospital, shows that 3,000 operations were performed during the year. The annual report of the Provident Dispensary Association, at Rochester, N. Y., shows that 1,119 patients were visited, and 1,808 prescriptions dispensed.—By the will of Mr. J. C. Kyle, of Topeka, Kans., \$10,000 is left to the Chris Hospital of that city. The Waukegan (Ill.) Hospital Association held a meeting January 14.—The fifteenth annual report of St. Joseph's Hospital, at Omaha, Neb., shows that 750 patients were treated in that institution during the past year. The pesthouse at Elizabeth, N. J., was destroyed by fire January 20. Loss \$1,000.—The Syracuse, N. Y., Dental Society is agitating the subject of a dental hospital in that city.

Society Notes.

ANNUAL MEETING.—The Twelfth Annual Meeting of the Fifth District Branch of the N. Y. State Medical Association will be held in Brooklyn on Tuesday, May 26, 1896. All Fellows desiring to read papers will please notify E. H. Squibb, Secretary, P. O. Box 760, Brooklyn.

THE NEW YORK COUNTY MEDICAL ASSOCIATION.—At its annual election held Monday, January 20, this association elected the following officers: President, Joseph E. Janvrin, M.D.; Vice-President, Herman J. Boldt, M.D.; Recording Secretary, Brynberg Porter, M.D.; Corresponding and Statistical Secretary, Nathan Gross Bozeman, M.D.; Treasurer, John H. Hinton, M.D.; For Member of the Executive Committee, for four years, John Shrady, M.D.

MILWAUKEE MEDICAL SOCIETY.—The annual meeting of this society was held Tuesday, January 14. The following officers were elected for the ensuing year: President, Dr. W. A. Batchelor; Vice-Presidents, Dr. Dwight Mereness and Dr. Ralph Chandler; Secretary, Dr. Gilbert E. Seaman; Treasurer, Dr. U. O. B. Wingate; Librarian, Dr. R. N. Hawley; Curator, Dr. A. J. Burgess.

ONEIDA COUNTY MEDICAL SOCIETY.—The quarterly meeting of this society was held in Utica January 14.—The annual meeting of the Toledo, Ohio, Medical Association was held January 10. The following officers were elected for the ensuing year: President, James C. Reinhart; Vice-President, William D. Stewart; Recording Secretary, Charles P. Wagar; Corresponding Secretary, Charles W. Newton; Treasurer, George A. Collamore; Librarian, Samuel S. Thorn; Member Library Board, Otto Landman; Executive Committee, W. C. Chapinan, E. C. Bodman, Wm. Cherry, James A. Duncan, C. H. Reed; Examining Committee, H. A. Root, B. Becker, J. Donnelly, Thos. Hubbard, Albert F. McVety.—The regular meeting of the Topeka, Kans., Academy of Medicine was held January 13.

Detroit Notes.

ON MONDAY, JANUARY 20, the Detroit Medical and Library Association listened to a paper by Dr. E. Fletcher Ingals, of Chicago, entitled, "Abscess of the Lung." The paper was discussed at length by Drs. E. L. Shurly and T. A. McGraw.

AT THE REGULAR MEETING of the Wayne County Medical Society, Thursday, January 23, Dr. C. B. Stemen, of Fort Wayne, Ind., presented the general outline and initiatory steps to the formation of the American University, speaking to the point in reference to the medical department of the same. The Doctor told what steps Congress had taken in the matter as to placing the naval and army departments together with certain available material in the Smithsonian Institute at the disposal of the students of this institution. The Doctor emphasized the point that the school would be post-graduate in all departments. In this particular, it would not interfere with any of the schools now in existence; it would simply be a step higher and would work in harmony with all existing institutions. The requirements for a degree in the medical department of this school would require the applicant to hold a B. A. certificate, together with a diploma for four years of study in medicine in some recognized medical school; but what the Doctor especially emphasized, as far as benefits to the profession went, was that the facilities were at hand in Washington for all the original investigation that anyone could desire in our chosen profession, and that these had already been guaranteed, to be placed at the disposal of the students. Dr. Stemen desired to learn the wishes and the wants of the profession in this important undertaking, and secure their coöperation. Dr. E. W. Jenks, in replying, agreed with the essayist as to the good to be derived from the establishment of the university and the importance of the undertaking, but thought the requirement of a B. A. certificate was much too high a standard. Dr. Arthur B. Holmes thought that the standard was a good one; that a man with a B. A. could listen to lectures with more

profit, being able to understand what was said much better than one that had not had a classical course. Dr. Hal. C. Wyman did not agree with the high standard required. He said that the farmer boy who was required to care for and keep in repair the farm implements was the one, that having completed his medical education, was able to manipulate the different mechanical appliances much better than his more fortunate colleague that had not had his former experience. Dr. John North, of Toledo, Ohio, spoke with considerable enthusiasm and complimented Dr. Stemen on his great undertaking and on the forethought of Bishop Hurst in making the appointment. Dr. E. T. Millegan and Dr. T. J. Parker commended the project. Dr. Kenneth Gunsolus also liked the idea of the university; but thought that it would not educate the people, and what we particularly needed was legislation by which only graduates could practice medicine.

HEALTH OFFICE REPORT for week ending January 25: Deaths under 5 years 39, total 91; births, male 58, female 56, total 114. Contagious diseases: Diphtheria, last report 27, new cases 7, recovered 10, died 2, now sick 22. Scarlet fever, last report 19, new cases 5, recovered none, died none, now sick 24. Smallpox, last report 3, new cases none, recovered 1, died none, now sick 2.

Cincinnati Notes.

THE MORTALITY for the week ending January 17 gives: Diphtheria 3, measles 4, typhoid fever 8, other zymotic diseases 4; cancer 7, phthisis 20, other constitutional diseases 6; apoplexy 5, bronchitis 11, gastritis 3, heart disease 4, meningitis 7, nephritis 5, peritonitis 2, pneumonia 20, other local diseases 19; violence 3, developmental 10; under 1 year 21; 1 to 5 years 17; all causes 141. Rate per 1,000 20.94. Corresponding week 1895, 117; 1894, 119.

THE STAFF of the Cincinnati Hospital have voted to increase the number of internes four and extend the limit of service to eighteen months instead of twelve.

DR. G. A. BUDD had an exciting encounter with a highwayman last week, in which his refusal to "throw up his hands" resulted in a bullet hole in his hat. The Doctor fired two shots at the robber, who unfortunately escaped.

J. A. BORSE, a Philadelphia drug broker, has been interviewed by Food Commissioner Luebbing regarding the cheap quinin the former has offered for sale; he stated, however, that he had sold none of it in Ohio nor in States which had laws against the sale of adulterated goods.

WHILE DRIVING from Milton to Belleville Dr. C. O. Probst, Secretary of the Ohio State Board of Health, was thrown from a buggy and painfully injured. Dr. Probst was in Milton investigating the recent outbreak of smallpox there.

DR. GILBERT I. CULLEN has been appointed surgeon for the Cincinnati, Jackson & Mackinaw Railroad for this vicinity.

THE OBSTETRICAL SOCIETY, of Cincinnati, at its regular annual meeting, at the Grand Hotel, Thursday evening of last week, elected the following officers: President, Dr. R. B. Hall; Vice-President, Dr. C. L. Bonnifield; Secretary, Dr. E. S. McKee; Treasurer, Dr. G. E. Jones.

DIPHTHERIA is prevailing to an alarming extent in West Alexandria.

AT THE MEETING of the Academy of Medicine held January 20, Dr. G. A. Fackler read a paper on "Some Fatal Cases of Typhoid Fever, with Post-mortem Findings," and reported a case of "Raynaud's Disease." Dr. Max Thorner read a paper on "Autoscopy of the Larynx and Trachea."

CHRIST'S HOSPITAL and Deaconess' Home are to close one floor of the hospital to curtail expenses.

THE CITY PHYSICIANS, of Covington, Ky., have applied to the city for an increase of salary, with the agreement that they will hereafter supply the medicines to the poor in tablet form.

DR. E. JOHNSON. Considerable interest has been aroused across the river in the case of Dr. E. Johnson. He lives at

Petersville, Ky., and was indicted at the last term of the circuit court because he continued to practice his profession without a certificate from the State Board of Health. Great interest was centered in the case, as it was thought it would determine the fate of other physicians now under indictment. Ex-Congressman George M. Thomas and J. Noel Johnson represented the defense. They contended that Dr. Johnson had fully complied with the law by securing affidavits from old citizens that he had practiced over thirty years; that the certificate was not granted was not the fault of Dr. Johnson, but the result of the arbitrary withholding of the same by the board. Commonwealth's Attorney Sallee took that view of it and dropped the case out of court. Johnson is bringing a \$10,000 damage suit against the board.

DR. JOHN PENNOCK GRUWELL, of Alliance, Ohio, a prominent member of the Society of Friends, died January 21 from an attack of la grippe. He was the oldest graduate of the Medical Department of the University of Pennsylvania.

Washington Notes.

WEEKLY REPORT OF THE HEALTH DEPARTMENT. The report of the Health Officer for the week ended January 20 is as follows: Number of deaths (stillbirths not included): White, 58; colored, 52; total, 110. Death rate per 1,000 per annum: White, 16.1; colored, 30.8; total, 20.8. Death rate per annum corresponding week last year, 18.8.

SURGEON GENERAL STERNBERG OPPOSES THE CRUELTY TO ANIMALS BILL. Surgeon General George M. Sternberg has written a letter to Mr. McMillan, chairman of the Senate committee on the District of Columbia, stating his objections to a bill lately introduced in the Senate for the prevention of cruelty to animals. He thinks that the provision requiring those who experiment on animals to hold a license from the Commissioners should be eliminated or modified so as to permit medical officers and others properly detailed for experimental work in any of the departments of the government service to prosecute such experiments without a license. After stating other objections to the measure, Gen. Sternberg concludes as follows: "So far as observation goes, I do not think there is any necessity for legislation upon this subject. In my opinion, it is a mistake to suppose that those engaged in scientific investigation or in teaching physiology are any less humane than the members of the Washington Humane Society, and the passage of an act placing them under the supervision of inspectors appointed by this society would be an unmerited reflection upon them."

DR. KING RESIGNS FROM COLUMBIA COLLEGE. Dr. A. F. A. King, Professor of Obstetrics in the Columbia University, has tendered his resignation from the staff of the Columbia Hospital, because he would not countenance the unjust treatment of a co-member of the staff by the lay members of the Board of Directors. Dr. King's course is cordially approved by the medical profession in Washington. A prominent member of the directors has asked for an amendment to the by laws which will preclude any member of the medical staff attending the meetings of the Board of Directors of the Hospital. The result of the tempest now in progress in the hospital is anxiously awaited.

MEDICAL BILL HEARING IN THE SENATE. At the hearing granted to the members of all medical schools for or against the medical practice bill Dr. Bussey spoke for the bill. He said that the statements and declarations which had been made were sufficient in themselves to prove the necessity of a law. The main points favoring the bill were as follows:

1. Laws of like character have been enacted by forty three States and Territories.
2. Absence of any uniform standard of medical education in this District.
3. Faculty of organizing medical schools in this District without any standard of education.

4. This District is the common rendezvous of charlatans of low grade schools.

5. A uniform grade of qualification will elevate the standard of medical education.

6. It will offer perfection to the community from charlatantry and imposition.

SANITARY EXAMINER APPOINTED.—Dr. G. M. Kober, the typhoid fever expert, has been appointed a medical sanitary examiner in the health department to perform such duties as may be assigned him by the health officer.

MEDICAL SOCIETY OF THE DISTRICT.—At the regular meeting of the society, held on the 22d inst., Dr. Bovee presented two cases of fibroid tumors complicating pregnancy. Dr. McCormick presented a gelatin dressing for use in skin diseases. Dr. W. W. Johnston, chairman of the Committee on Public Health, presented an exhaustive and instructive report. He went into the subjects of typhoid fever, malarial diseases, smallpox, water supply and filtration, sewers and sewage disposal. He gave a complete history of the health of the District during the year of 1895. The report was adopted and a vote of thanks of the society was tendered the Committee. A special meeting of the society was held at 2 o'clock the same day, to take action on the death of Dr. W. E. Wolhaupter. Suitable resolutions of respect were adopted.

THE PUBLIC SERVICE.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending January 25, 1896.

Surgeon C. A. Siegfried, detached from the "Texas" and ordered to the "Columbia."

Surgeon W. G. Farwell, detached from the "Columbia" and placed on waiting orders.

P. A. Surgeon J. A. Guthrie, detached from the "Texas" and ordered to the "Katahdin."

Change of Address.

Ashmead, Albert S., from 270 W. 43d Street, New York, N. Y., to 205 Franklin Avenue, Norristown, Pa.

Bridge, Norman, from Los Angeles to 106 Grand Avenue, Pasadena, Cal.

Gedge, D. M., from San Francisco, Cal., to Honolulu, H. I.

Joralemon, J. C., from Toledo, Iowa, to Los Angeles, Cal.

F. H. Lawther, from Chicago, Ill., to Oskaloosa, Iowa.

Welch J. P., from St. Johns to Holbrook, Ariz.

Woodburn, F. C., from Ravenswood, Ill., to Indianapolis, Ind.

LETTERS RECEIVED.

ORIGINAL ARTICLES.

CONSERVATISM IN OVARIOTOMY.

BY HOWARD A. KELLY, M.D.

PROFESSOR OF GYNECOLOGY IN THE JOHNS HOPKINS UNIVERSITY.
BALTIMORE, MD.

I have recently received two vigorous letters, which I enclose, from friends who are doctors, upon the ethical status of the operation for the removal of the ovaries. These letters have brought vividly to mind a note which I published in the *American Journal of Obstetrics*, for February 1893, entitled "The Ethical Side of the Operation of Oöphorectomy;" I have gone over the ground once more from the standpoint of almost three years' growth in gynecology, to see what positive advances have been made in answer to this burning question. Both of the letters are from highly valued friends, for whose opinions I have a profound respect, and in whose judgment I place full confidence; I feel under obligation to reply to them in such a way as shall effectually promote the end in view. One of the letters, the second one, is from a distinguished physician, the leading practitioner in one of our large cities, and a man of national reputation. I publish both just as I have received them, believing them to be more valuable in this form than if I had asked the writers to make alterations in accordance with any minor criticisms I might have to offer.

Conservatism, the appeal of my correspondents to conscientious gynecologists, is undoubtedly the progressive spirit in gynecology; exsective and amputative gynecology has gone to its extreme limits, and the more thoughtful surgeons looking at all the questions involved, in their broader aspects, have already sounded the keynote of the new advance. To put the matter clearly before the minds of practitioners in general, I would cite categorically the following conservative procedures, which replace radical measures:

1.—Resection of diseased ovaries and opening and draining tubes, as urged by Dr. Wm. M. Polk, of New York, in the *American Journal of Obstetrics*, July, 1894, Vol. xxx, pp. 1-15, and in the *Transactions of the American Gynecological Society*, 1893, Vol. xviii, p. 175.

2.—Myomectomy as a substitute for hysteromyomectomy, by Dr. E. C. Dudley, of Chicago, in the *Transactions of the American Gynecological Society*, 1894, Vol. xix, p. 126.

3.—Opening and draining pelvic abscesses posterior to the uterus. See "Conservative Treatment of Pyosalpinx," by Cornelius Kollock, in *Transactions of the Southern Surgical and Gynecological Association* Vol. vi, p. 43. Also "Conservative Surgical Treatment of Para- and Peri-uterine Septic Disease" by Fernand Henrotin in the *Transactions of the American Gynecological Society*, Vol. xx, p. 223; reviewed editorially in the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION*, June 22, 1895, p. 983.

4.—Vaginal drainage in some cases of extra-uterine pregnancy. See my article in *An American Text-book of Obstetrics*, Philadelphia, 1895.

5.—Excision of both large and small parovarian cysts, without sacrificing ovary and tube, in my own practice not yet reported.

I do not wish to dwell on these operations now, for it is rather my object to try to arouse a more general feeling of interest in the broad moral bearings of the entire question. In doing this, I dare not omit the most fruitful of all causes of the unnecessary mutilation of women, and that is, the large numbers of men all over the country who are entering upon this specialty without any adequate preparation, and are yet anxious at as early a date as possible to "make a record." I have seen repeated examples of this reckless exsective surgery, and it is my privilege every week to save women who have in some instances traveled long distances to get further advice. Only yesterday I saw a hysterical girl about 18 years old, drugged with morphin, and without any pelvic disease whatever, whose physician thought that ovariectomy was clearly indicated. A patient, now under treatment for a mild trigonitis (inflammation of the vesical trigonum), came to me because her previous attendant, after some treatments applied to her ovaries through the vault of the vagina, declared that her ovaries and tubes were diseased and must come out, or he could not cure her. And yet she has not a trace of pelvic disease outside the little trouble in the bladder. And so on, I might add case after case *usque ad infinitum*.

I shall not, in this brief appeal to higher morals, analyze causes minutely, but I can not help adding that apart from the question of integrity involved, these men have never thoroughly learned, at the hands of a skilled clinician, the technique of the bimanual examination; they make their diagnoses symptomatically, and hence the frightful errors. Nor would I lay all the blame on the untrained men; even the best men have erred, but they have had the saving grace to report their errors for the benefit of others. As evidence of this, I pick up with little effort, the following cases of pregnancy occurring in women, the first six of whom had been advised to have their ovaries and tubes removed, but had refused, and twenty-four of whom under the ordinary procedure of the day would inevitably have been made sterile:

Women refusing operation who afterward became pregnant and bore children: Dr. Wm. Goodell, two cases (*Clinical Gynecology*. Keating and Coe. Introduction, p. 10). Dr. Archibald MacLaren, one case. (*Trans. Amer. Gyn. Soc.*, 1893, vol. xviii, p. 334). Dr. Charlotte B. Brown, one case ("Rest, a Therapeutic Means in Gynecology." Read before the Medical Society of California, April, 1895). Dr. H. A. Kelly, two cases (unreported).

Cases of abdominal operations on ovaries treated

conservatively, followed by pregnancy: Dr. Wm. M. Polk, nine cases (*Amer. Jour. Obst.*, July, 1894, vol. xxx, p. 1). Dr. Robert A. Murray, six cases (See Dr. Polk's paper, just cited). Dr. B. McMonagle, one case (See Dr. Polk's paper). Dr. B. F. Baer, one case (See Dr. Polk's paper). Dr. Frank Talley, one case (*Amer. Gyn. Obst. Jour.*, March, 1895). Dr. H. A. Kelly, three cases (unreported). Dr. Matthaei, six cases, five children (*Zeitschr. f. Geb. u. Gyn.*, vol. 1, part 2).

Dr. Polk had six cases of inflammatory disease in which he conserved the appendages, with the result of nine pregnancies. Dr. McMonagle's case was altogether remarkable and ought to be carefully studied by every gynecologist. In one of my own cases I opened and drained a large right ovarian abscess, and pregnancy occurred within two years. We have here then, as a result of this conservatism, either by the insistence of the patient, or the election of the surgeon, in twenty-nine women thirty-two childbirths. (One of Dr. Polk's patient's, "wearying of maternity," secured a criminal abortion to rid herself of her second conception after the operation.) These facts need no comment, and speak volumes for the recuperative powers of these organs in disease. Another moral consideration of great weight is the necessity in all cases of making the woman clearly understand the effects of the operation on her whole life; undoubtedly many women accept the alternative of an operation in utter ignorance of its full consequences. The especial importance of this question to unmarried women may be seen when we reflect that about 20 per cent. of all women do not marry, and that these are precisely the cases most likely to suffer at the hands of the unskilled surgeon. He is unable to make a clear diagnosis owing to physical obstructions, and so after a time, if the patient continues to suffer pain, he hazards a conjecture that the ovaries are diseased and decides that they must come out.

There is another question raised by these letters which ought to be considered in the interests of pure morals, and that is, the attitude of the physician toward the prevention of the infection of wives by their husbands. I know of no more distressing and pitiful sight than the pure women I often see whose lives have been wrecked by a marital infection. Just what course to pursue in the particular instance, the surgeon must determine for himself; but one conviction ought to rest on every man in the profession, and at all times find unhesitating expression, and that is, that there must not be a double standard of morals. What is wrong for a woman to do is wrong for a man to do. A female prostitute is as good as a male prostitute, and ought to command the same consideration and respect. This is a wise policy which looks to the future of the race, and its quickening influences and sound scientific results will surely be felt by our followers. If men were, as a class, as chaste as women, many of the problems of gynecology would solve themselves.

With this introduction, I will now let my correspondents speak, only adding that I feel in entire sympathy with the spirit of the letters.

LETTER I.

The operation of ovariectomy has two aspects, the ethical and the medical, both of which, I think, are likely to be lost sight of by the ambitious young surgeon who sums up the whole matter so cavalierly, "recovery uneventful." On the ethical side, an uneventful recovery may mean for the woman a life of unhappiness, and it is an open question whether the sum total

of uneventful recoveries does not increase immorality among men.

The function of menstruation is a natural process most intimately associated with the highest and holiest feelings of womanhood. Most women rejoice in potential motherhood, and, when the time comes, gladly take their lives in their hands to accomplish it. I have personally known no exceptions to this rule, except those unfortunate women who were married to sensual and brutal husbands. A sensible woman wants to be well, to keep all the organs of her body in good condition, so as to perform all the duties of life. One of the most important of these, and precisely the one that comes nearest her heart, is the bearing and rearing of children. Now, the operation of ovariectomy places the marriage relation distinctly on a lower plane, and I am surprised to have seen this view expressed but once, even by the conservative surgeons. The grossness of the physical union in marriage is redeemed by its moral significance, the desire for children. This desire is stronger in women than in men, so strong that when I consider all the suffering of women in all the ages of the world for it, I am appalled. Think for one moment what women have endured, from the brutality of men, from the ignorance and blunders of medical science, from a pitiless and degrading theology that denominates the pangs of maternity, "the curse of Eve." Men want children, too, but they do not care so much about them as women do, they do not make sacrifices for them half so willingly.

The existence of prostitution shows the difference between men and women as to the sexual instinct when the hope of children does not enter into it. Women prostitutes are almost wholly from the working-classes; they are often ignorant country girls who have first been betrayed, and who are then forced to live in shame, because the hard economic conditions of life for women prevent them from gaining an honest livelihood. An English barrister working among the poor of London estimated last winter that 20,000 prostitutes in London would gladly give up the calling, if they could find reputable employment. And a late utterance from one of the physicians on Blackwell's Island, New York, is, that the most practical means of meeting the social evil is to open up avenues of employment for women. Men prostitutes, on the other hand, are from every class, and pay; they do not debase themselves for the means to live. It is unhappily too true that a great many men have no notion of endearment or of shame in the sexual life, and this difference between men and women bears upon the operation of ovariectomy in two ways. In the first place, it is morally indefensible to mutilate the wife for the sins committed by the husband before marriage. It adds frightfully to the physical disabilities of women, and it is a positive encouragement of vice. Every physician knows how many pure women fall victims to their husbands in this way, and it is the duty of every reputable physician to the community he lives in to discourage ovariectomy, except for most urgent reasons. "The wages of sin is death," and one way to enforce this wholesome doctrine upon unchaste men is to leave them with ailing wives. This may seem hard on the women, but it is by no means proved that ovariectomy has not more ills in its train than good. On general principles, a woman is better off mentally, morally, and physically, if menstruation is allowed to run its natural course.

As to the husbands who are respecters of persons, and who remain true to their wives made sterile in this way, their lot is a hard one. I do not believe it is possible for a husband to love his wife as is her due knowing that she is physically incapable of becoming the mother of his children. And no wife can live so intimately without recognizing a difference, so that in addition to her woman's sorrow in childlessness, she is made to feel herself hopelessly outside of her husband's feelings. In mutilating her the surgeon may have made her as hateful to her husband's sight, as if she had some frightful physical blemish. How much unsexing women may have to do with increasing immorality among men, I have no means of judging, but the popularity of ovariectomy and the propensities of men make the situation serious enough for the conscientious surgeon. Nor do I know what the ultimate effect of removing the ovaries is upon the woman's sexual feelings. Dr. Goodell thought at first it made no difference, but came to change his views. Many able physicians agree with him that the operation deadens the sexual sense. This is just one of the points that gynecology must clear up. It is certainly an unusual man who marries a castrated woman. Moreover, marriage based on sense, like marriage without love, is practically a life of unchastity. This feeling dominates every woman who declines to marry a man because she can not love him as a wife should. She is unwilling to live a life of legalized prostitution, which is in plain terms simply what a great many marriages are.

So far I have spoken only of the castration of married women,

but I think the operation is even more unjustifiable when performed on a single woman, and should never be resorted to except when it is a choice between castration and death. To remove a young woman's ovaries or womb and then to tell her that she is incapable of marriage physically is a barbarous cruelty. Ethically, in mutilating a virgin in this way, the surgeon may have taken from her all chance of happiness on earth, and even her hope of heaven. Economically, as the world is constructed, many women have no other prospect in life than marriage. Besides, unless a woman has means, or education, or unusual strength of character, a single life is insupportable. And, I take it, these are not the qualities that are oftenest met with in the gynecologic wards of our hospitals. On the medical side Dr. Lusk puts the case much better than I can. Ovariectomy is not a cure; it is a makeshift, and in so far is a confession of weakness. Moreover, while aseptic surgery is undoubtedly a great advance on the old methods, it is not difficult to acquire. It is vastly easier to cut out a woman's womb than to make and keep it a healthy organ. And this is precisely the problem that is before gynecology as a science. It must first find out a way to produce a race of women with healthy generative organs, and second, it must learn how to keep all this delicate machinery in order under the immense strain of function put upon it. In many instances I believe the world would be better off if these ambitious young surgeons were put to their books. We need better trained general practitioners, not more men who can perform abdominal surgery successfully.

Now gynecology is a brilliant specialty, it offers great rewards in reputation and is money. A great many young men of all grades of intelligence and morals, are rushing into it. Naturally, they look to you as their exemplar, for your success in it has been exceptional. This is why I urge the matter upon your attention. I think your responsibility is very great. Personally, my trust in your good judgment and your heart is absolute, but these are unknown qualities in the young gynecologists who are following in your footsteps. Every day all over the land women are being mutilated at the hands of ambitious young men who are anxious to report to the profession that they can do ovariectomy or hysterectomy. I feel sure that not a few of these helpless victims might be saved present pain and future misery by a word of warning from you.

LETTER II.

You know that I feel and have felt very strongly on the subject of your letter. The time has been when to express such views as you express would condemn one to charges of "old fogyism" or ignorance. But ever since the rage for ovariectomy took possession of the medical mind, I have had an invincible repugnance to the castration of women, and have often had hard work to restrain myself when statistics "of 100 cases without a death," "my first year's work in ovariectomy," etc., were read *ad nauseam* before our Medical Society. I shall never forget the night when one of our "best operators" handed round on a plate the two ovaries of a woman recently castrated: one had a small cystic tumor about the size of an apple, while in the other the cyst was not larger than a marble. The reporter dilated on the physical perfection of the woman, on the fact that she was about to be married, and then told of his successful operation. Just think of it! And is not this gynecology in its infancy, when to cure a minute cyst or to prevent its growth, the whole womanhood, the whole happiness and all the life of this woman were irretrievably ruined? And yet no one there said one word of disapproval, but all sat and admired the skill of this destroyer of everything that makes a woman's life worth living.

A wedding took place here this spring between a recently castrated girl and a young man who had been engaged to her for a long time. Do you not think that he would rather have married her with one ovary left, even if there were a probability of ill health and suffering? The girl, from being slender and young looking, in six months had grown stout and much older and was by no means improved in appearance.

This is all but a prelude to saying how much pleased I was at the way you presented your case against the operation. I agree with you that ovariectomy, before or after marriage, ruins a woman in all the essentials of womanhood. It makes of marriage just what you say. Just think of the feeling which a man must have when he marries a mutilated woman! What does he marry for? There can be no hope and no happiness in such a union; there is no end to look forward to; there is nothing which makes marriage perfect and holy.

I wish your views could be brought to the inner consciousness of the gynecologists of the country. I wish they could be made to see and feel: but I fear many of them will think your opinions beyond the domain of science and practice and will

pass them by. And then it touches the pockets. Ovariectomies are a source of income; many have grown rich on them and you strike at the root of a very thriving industry. But you should not drop your task for all this, and the fact that Dr. Kelly sympathizes with your efforts should encourage you to say and to do something to stem the torrent of mutilation.

VAGINAL HYSTERECTOMY—TWENTY-ONE
CONSECUTIVE, SUCCESSFUL CASES.

BY CHARLES GILBERT DAVIS, M.D.

CHICAGO, ILL.

In looking back over the history of surgical progress it is interesting to note the process of evolution which has so gradually brought order out of chaos and from the crude methods of the past evolved the brilliant results which to-day are crowning modern surgery. It is right and just that much credit should be given to antisepsis and yet a large percentage may be justly attributed to improvement of technique and simplicity of procedure. This is an age of brevity. All the world is seeking a more direct route to the point of destination. Unnecessary complications are avoided. To no part of surgery do we find these facts more applicable than in that which relates to the abdominal and pelvic regions. It is unnecessary to state that far too many operations have been performed on the organs in these localities and that many blunders have been necessarily committed. But this great experience has not been without its beneficial lesson; we are approaching simplicity and the outlook for the future is brighter. For many years several intelligent and far-seeing surgeons have intimated that the vaginal route was far superior to the abdominal for many of the operations on the uterus and adnexa. But it has been apparently difficult to abandon the older method for the new and more successful.

Vaginal hysterectomy, as a surgical operation, dates back to the early centuries of the Christian era, but it can not be said to have been thoroughly elucidated until the year 1813, when it was performed by M. Laugenbeck for cancer. Even then his medical confrères refused to believe that he had performed this operation, and it was not until some years later, when his patient died and a post-mortem was held, that his words were verified. The operation wavered awhile in popular favor and then fell into discredit when Freund, of Breslau, advocated abdominal hysterectomy. The bad success of this again brought the vaginal operation to the front in the year 1878, largely through the advocacy of Czerney, of Heidelberg. Since that period it has been gradually gaining ground, and to-day is rapidly supplanting the abdominal method as a relief for many of the pathologic conditions afflicting the uterus and its appendages. It may be employed:

1. In all cases where we determine to perform double oöphorectomy.
2. In double pyosalpinx or salpingitis.
3. In single oöphoro-salpingitis where we have unyielding, chronic metritis.
4. In severe displacements near the menopause, and all others not yielding to treatment.
5. Tumors of the uterus, interstitial or subperitoneal, not exceeding a child's head in size.
6. In all cases of malignant diseases of the fundus and cervix, when not involving the vaginal or pelvic walls.
7. In small cysts and other growths of one or both ovaries and tubés near the menopause.
8. In all cases of chronic peri-uterine

phlegmasia, with or without suppuration, not yielding to other treatment.

There are two distinct methods of performing this operation. In one the broad ligaments and arteries are secured by ligatures tied to different sections laterally as the operation proceeds. This, as the operation most frequently done by the German surgeons, may be designated as the German method. In the other no ligatures are used and the broad ligaments and arteries are secured by clamps or catch-forceps, which are allowed to remain for forty-eight hours. This is the operation usually performed in France and may be appropriately called the French operation. Its thorough establishment as a legitimate surgical method is undoubtedly largely due to the wisdom and experience of that eminent surgeon Péan, of France. Each of these methods has its adherents. I believe from observation and experience, that the practice of hemostasia by forcipressure is superior and can be adapted to a greater variety of conditions.

In a normal case of hysterectomy I usually proceed as follows: For five days preceding the operation the patient has a daily bath of warm water and white castile soap followed by brisk and thorough friction. The vagina is also irrigated morning and evening with a sublimate solution (1:5,000). The day before the operation a mild laxative is administered and a thorough enema given on the following morning. The patient is anesthetized and placed on the operating table in the dorso-sacral position. I prefer this to the left lateral position as giving a more symmetrical view of the organs concerned. An assistant introduces the catheter, being careful to entirely evacuate the bladder. This is quite essential as lessening the risk of wounding that organ. The vulva and vaginal cavity are again lubricated with white castile soap and warm water and douched with the sublimate solution (1:5,000). A pair of ordinary vaginal retractors are now introduced antero-posteriorly and held by two assistants, who at the same time support the limbs with the thighs well flexed on the abdomen. Using a pair of light vulsellum forceps the extremity of the cervix is now grasped with the left hand and the uterus drawn down, while with a bistoury in the right a curved incision is traced anteriorly and posteriorly to the os, within an eighth of an inch of that orifice, meeting on each side a vertical incision of about half an inch in length. With a few strokes of the curved scissors and with the end of the index finger these flaps are rapidly dissected back, before and behind, down to the attachments of the broad ligaments. The uterus is now grasped by the strong Museux forceps and, by using some force, brought down while we apply on each side the clamps. After these are placed, one at a time and well locked, we may with the straight scissors cut loose the attachments of the broad ligaments between the forceps and the uterus. On making traction the uterus is now descended still more and if necessary we may apply another set of forceps and cut the remaining sections of the broad ligaments. At this period of the operation we may find it convenient to remove the ordinary retractors and employ those especially designed by Péan. They permit a better view of the deep pelvic region. In many instances when the organ is movable only one pair of clamps will be necessary for the ligaments. The dissection is now carried on beyond the fundus anteriorly and poste-

riorly and making traction on the cervix downward and backward, the body of the uterus is reached with the hook or crochette and easily everted anteriorly. For clamping the ovarian artery and tubes I usually prefer the curved forceps of Péan, as they can be readily adjusted without protruding into the peritoneal cavity. The ovaries, if they descend into the wound, are clamped and cut away, but if adherent and difficult to reach they are not to be disturbed. Their functional activity ceasing immediately after the removal of the uterus makes their removal a matter of minor importance.

The operation is now virtually finished. No stitches are required to close the perineum or to attach it to the uterine flaps. Better drainage is secured by leaving it open. The wound may be douched with a sublimate solution and then with sterilized water. The clamps are well looked after to see if they are securely locked and all minor points of oozing checked with hemostatic forceps. The wound is now dusted with powdered iodoform, and gauze of the same antiseptic is loosely tamponed in the vagina between and around the bundle of forceps so that they are completely enveloped in the antiseptic dressing. The whole is now surrounded with absorbent cotton and sterilized gauze. A catheter should be left in the bladder and a tube in the rectum. The patient is placed in bed, the bundle of forceps resting on a pillow made for that purpose, and hot bottles around the extremities. If there is much pain an eighth of a grain of morphin with atropin is given once or twice hypodermically in twenty-four hours. The amount may be slightly increased if there are no symptoms of vomiting. The second day, if the stomach is favorable, milk whey may be given. In forty-eight hours the clamps are removed. In doing this a slight rocking or rolling motion may be given to the instrument so as not to open the arteries. The dressing having been entirely removed, a warm douche of sterilized water may be given at once. I consider this very beneficial, in fact, quite necessary as a guard against sepsis. In the administration of this douche much care should be taken that the fluid does not pass beyond the pelvic region and so enter the abdominal cavity. Should this happen, septic material may be conveyed, and the entrance of the fluid into this region at this time is liable to produce great pain and symptoms of shock. Twice I have seen alarming symptoms arising from this cause. This accident may be prevented by making deep pressure, with one hand, above the pubis until the douche is terminated. After the douche the vagina is lightly tamponed with iodoform gauze. No speculum should be introduced for fear of distending the parts and causing hemorrhage. The douche and dressing should be repeated twice daily. The patient may now have soup, broth or gruel. The bowels are moved by an enema on the third day. On the fourth day there may be given solid food, for the patient is on the road to rapid recovery. *Alcoholics should not be given.* I regard their administration in surgical operations as detrimental. Alcohol is an anesthetic and in no sense of the word a stimulant.

But hysterectomy is not always such an ideal operation as I have pictured. The adhesions may be great and so dense as to prevent that rapid descent of the uterus which so facilitates its removal. Or we may not be able to readily antvert or retro-

vert it before applying the clamps to the tubes. In this case it is sometimes necessary after denuding anteriorly and posteriorly, to bisect the organ with the straight scissors and then to proceed slowly to remove one section at a time. Again, it may be necessary to resort to morcellation; particularly is this the case when we have to deal with uterine fibroids. This process is not usually difficult with the morcellation forceps and curved hysterectomy knives. Indeed, I regard this as one of the most legitimate methods of removing all moderately sized uterine fibroids.

The following consecutive cases are illustrative of the above description:

Case 1.—Mrs. E. E., age 36 years; admitted to Chicago Baptist Hospital, Oct. 8, 1894; married eighteen years; has had two children, the youngest being 13 years of age. No miscarriages; excessive menstruation for several years; pain in abdomen. Diagnosis, uterine fibroid, size of an Osage orange. Operation, vaginal hysterectomy by morcellation, Oct. 10, 1894. Dismissed, Nov. 4, 1894, cured.

Case 2.—Mrs. T. D., Dakota; age 33 years; admitted to Chicago Baptist Hospital Dec. 10, 1894; married six years. Never pregnant; menstruation painful; examination revealed tumor; has suffered for many years with utero-ovarian neuralgia; much treatment but no permanent relief. Diagnosis, uterine fibroid. Operation, vaginal hysterectomy, by morcellation, Dec. 12, 1894. Tumor the size of an egg. Dismissed, Jan. 21, 1895, cured.

Case 3.—Mrs. J. S., Chicago; age 48 years; admitted to Chicago Baptist Hospital Dec. 18, 1894. Irregular menses and much abdominal pain. Diagnosis, uterine fibroid. Operation, vaginal hysterectomy, by morcellation, Jan. 9, 1895. One large tumor the size of a small child's head and fundus of the uterus studded with numerous smaller ones. Dismissed, Feb. 27, 1895, cured.

Case 4.—Mrs. W. K., Chicago; age 51 years; admitted to Chicago Baptist Hospital Jan. 16, 1895; married thirty-seven years and mother of eight children, the youngest 10 years of age. Had four miscarriages; passed the menopause two years ago. For several years has suffered with severe pain in the uterine region; leucorrhea copious and offensive. Uterus enlarged to four times its natural size. Has been treated by numerous physicians without permanent benefit. Diagnosis, chronic metritis. Operation, vaginal hysterectomy, Jan. 17, 1895. Dismissed, Feb. 27, 1895, cured.

Case 5.—Mrs. F. J., Chicago; age 25 years; admitted to St. Mary's Polish Hospital Dec. 18, 1894. Had been confined ten weeks previously. Examination revealed bilateral laceration extending beyond the internal os. A part of the cervix was completely torn away. Both ovaries enlarged and painful. Constant nausea, vomiting and irregular movement of the bowels. In view of the impossibility of restoring the integrity of the womb it was decided to perform vaginal hysterectomy, and this operation was done Jan. 30, 1895. Convalescence was slow. At the end of the second week, while giving the usual evening dressing to the wound, a slight hemorrhage occurred, which at first appeared threatening, but completely subsided with hot douches. Dismissed Feb. 30, 1895. The patient has been recently seen and is found to be enjoying good health.

Case 6.—Mrs. A. F. W., Chicago; age 40 years; admitted to Chicago Baptist Hospital Jan. 6, 1895. Married twenty-two years; has had three children and four miscarriages. Has suffered for several years with pain in pelvic and ovarian regions. Examination revealed the fundus of the uterus enlarged and increased to about twice its normal depth. Diagnosis, interstitial fibroid. Operation, vaginal hysterectomy, Jan. 30, 1895. Dismissed, March 8, 1895, cured.

Case 7.—Mrs. C. L. M., Chicago; age 40 years; admitted to Chicago Baptist Hospital March 2, 1895; married at 22 years of age. Has had two children, the youngest 11 years of age. Has never been well since the birth of last child. Menses painful and profuse. Has suffered terribly with utero-ovarian neuralgia, and as a result the entire nervous system is disturbed. Fundus of the uterus enlarged and the depth increased to over four inches. Diagnosis, interstitial fibroid with cystic ovaries. Operation, vaginal hysterectomy, March 3, 1895. Diagnosis confirmed. Tumor the size of a goose egg. Dismissed, April 9, 1895, cured.

Case 8.—Mrs. C. H., Somonauk, Ill.; age 54 years; admitted to Chicago Baptist Hospital March 2, 1895; married thirty-four years. Has had six children, the youngest 18 years of

age. No miscarriages; no regular menstruation for two years; had a bloody discharge from the vagina after any unusual exertion. Constant pain in the lower portion of the abdomen. For the last six months symptoms have been greatly increased. Examination indicated presence of fibroid tumor attached to the fundus of the uterus, the whole mass appearing to be the size of a child's head. Operation, vaginal hysterectomy, by morcellation, March 3, 1895. Diagnosis confirmed. Dismissed, April 8, 1895, cured. Her husband has written me recently that her health is better than for many years.

Case 9.—Mrs. W. M. N., Keota, Iowa; age 49 years; admitted to Chicago Baptist Hospital March 19, 1895; married twenty-six years. Has had three children, the youngest 16 years of age. No miscarriages; menstruation has been irregular for the last six months. For more than two years has suffered from pain in rectum, pelvic and ovarian regions. Leucorrhea; examination revealed uterus enlarged and a cyst the size of an orange apparently attached to the left ovary. Diagnosis, chronic metritis with cyst of left ovary. Operation, vaginal hysterectomy, with the removal of both ovaries and cyst attached to left one, April 17, 1895. Dismissed, May 13, 1895, cured.

Case 10.—Mrs. E. W. C., Chicago; age 26 years; admitted to Chicago Baptist Hospital April 13, 1895; married five years. Has never borne a living child. Miscarried at the third month about four and a half years ago; menstruation regular; leucorrhea profuse, yellow, creamy and irritating; has suffered pain in the pelvic region for three years. Has had much treatment without benefit. Diagnosis, salpingitis with metritis. Operations, vaginal hysterectomy, April 17, 1895. Owing to excessive inflammatory attachments it was necessary to remove the uterus by morcellation. The operation was tedious and difficult. Dismissed, May 14, 1895, cured.

Case 11.—Mrs. B. L., Chicago; age 20 years; admitted to Chicago Baptist Hospital May 27, 1895; married two years. Has never been pregnant; suffers great pain before each menstrual period; leucorrhea creamy and profuse; lancinating pain in the region of the ovaries, particularly the left. Diagnosis, chronic salpingitis. Operation, vaginal hysterectomy, May 29, 1895. Dismissed, June 17, 1895, cured.

Case 12.—Miss E. A. S., Chicago; age 29 years; admitted to Chicago Baptist Hospital May 1, 1895. Has suffered from dysmenorrhea for fifteen years, and during all that time has never been free from pain in the pelvic region; leucorrhea profuse and excoriating; has frequently been confined to bed for weeks at a time with pelvic inflammation. Diagnosis, oöphoro-salpingitis. Operation, vaginal hysterectomy, by morcellation, June 19, 1895. Operation very difficult owing to the numerous attachments. Dismissed, July 17, 1895, cured.

Case 13.—Mrs. J. O. P., Minneapolis, Minn.; age 50 years; admitted to Chicago Baptist Hospital June 24, 1895. Has borne two children, the youngest 23 years of age. Menstruation has continued and grown more profuse, amounting at times to a hemorrhage. Watery leucorrhea. Examination revealed the neck of the uterus enlarged, patulous and nearly absorbed with a spongy growth. Constant pressure with shooting pains. Diagnosis, carcinoma. Operation, vaginal hysterectomy, June 26, 1895. Dismissed, July 31, 1895, much improved in health and apparently cured. A message from this patient one week ago says that her health is perfect.

Case 14.—Miss M. S., Valparaiso, Ind.; age 16 years; admitted to Chicago Baptist Hospital Aug. 24, 1895. Three years ago suffered from an accident, was injured in the abdominal region and since then has suffered much pain through the ovaries, particularly the left. Menstruation very irregular, and during this time had excruciating pain in the left ovary. General nervous system much disturbed; leucorrhea profuse; suffers much; no treatment has given relief and her parents requested an operation. Patient sent to me by Dr. Vincent, of Valparaiso, Ind. Diagnosis, cystic ovaries with salpingitis. Operation, vaginal hysterectomy, Aug. 28, 1895. The right ovary was found in a state of cystic degeneration and removed. The left, owing to its being imbedded in inflammatory tissues was left. Dismissed Sept. 28, 1895. Pain in the ovarian region entirely gone. Nervous symptoms very much better and gradually improving.

Case 15.—Mrs. W. N. M., Emporia, Kan.; age 26 years; admitted to Chicago Baptist Hospital Sept. 5, 1895; married seven years. One child 6 years of age. No miscarriages. Family history good; had good health up to period of birth of child. Perineum was badly lacerated during child-birth. General health began to deteriorate and she suffered with severe pain in the region of the pelvis. In 1894 had the right ovary removed by laparotomy in Kansas City. Operation gave no relief. Menstruation was irregular and painful. Constant pain in the region of the ovaries and uterus. Examination revealed

chronic metritis and salpingitis. Operation, vaginal hysterectomy, with removal of left ovary and tubes, Sept. 11, 1895. Dismissed, Oct. 31, 1895, cured. A recent letter from this patient tells me she has not had such good health for many years.

Case 16. Miss L. P., Boulder, Colo.; age 28 years; admitted to Chicago Baptist Hospital Sept. 28, 1895. Began to menstruate at 13 years of age and since that period has never had good health. Great disturbance of nervous system. Complains constantly of backache and pain in the lumbar region. Had the left ovary removed four years ago and the uterus curetted twice in Kansas City. Suffers now from constant pain in the region of the right ovary. Menstruation regular but very painful, with increased disturbance of nervous system. Leucorrhea yellow and offensive. Diagnosis, chronic metritis with salpingitis. Operation, vaginal hysterectomy with the removal of the right ovary and tubes, Oct. 2, 1895. Patient still in hospital and the nervous system slowly but gradually improving.

Case 17. Mrs. M. L., Chicago; age 46 years; admitted to St. Mary's Polish Hospital Sept. 11, 1895. Has had no children. For a number of weeks has had an almost constant flow; much pain. Had curettement and local treatment by family physician which failed to give relief. The uterus was found enlarged and covered with a fungus, patulous growth and had every appearance of carcinoma. An immediate operation was advised. Vaginal hysterectomy was performed Sept. 28, 1895. Recovery was rapid. Dismissed, Nov. 11, 1895, apparently cured.

Case 18. Miss D. M. K., Fort Wayne, Ind.; age 31 years; admitted to Chicago Baptist Hospital Oct. 14, 1895. Two years ago had two operations in which the uterus was dilated for stenosis and displacement. Excruciating pain with menstruation. Diagnosis, cystic ovaries. Operation, vaginal hysterectomy, Oct. 16, 1895. Dismissed, Nov. 15, 1895, cured, with wonderful improvement of health and strength.

Case 19. Mrs. J. T., Chicago; age 22 years; admitted to St. Mary's Polish Hospital Nov. 3, 1895. Two children. Menses regular but painful. Suffered from muco-purulent discharge for the last year and a half. Examination revealed bilateral laceration of the cervix, ovaries prolapsed and cystic. Diagnosis, chronic metritis with cystic ovaries. Operation, vaginal hysterectomy, Nov. 24, 1895. On removing the clamps in forty-eight hours the wound was found apparently in good condition. After administering the douche the vagina was lightly tamponed with iodoform gauze and the patient placed in bed. In a few minutes it was discovered that the dressings were saturated with fresh blood. She was immediately placed on the operating table, the dressings removed and a severe hemorrhage was discovered from the right uterine artery. Distending the vagina with the retractors the clots were washed away and the bleeding vessel grasped with two clamps. The dressing was renewed and the clamps left in position for an additional forty-eight hours, at the end of which time they were removed without the recurrence of hemorrhage. Slight parotiditis at the end of two weeks. From this time she made rapid recovery and was dismissed, Dec. 18, 1895, cured.

Case 20. Miss M. B., Chicago; age 21 years; admitted to Chicago Baptist Hospital Nov. 24, 1895. During four years has suffered constant pain in the back and region of the ovaries. Bearing down with painful micturition. Examination revealed an enlarged condition of the uterus with painful swellings on either side in the region of the fallopian tubes. Diagnosis, uterine fibroma with pyosalpinx. Operation, vaginal hysterectomy, Nov. 27, 1895. Diagnosis was confirmed and a large quantity of pus, at least a pint, was removed from the tubes. The patient made favorable and rapid progress. Dismissed, Jan. 12, 1896, cured.

Case 21. Mrs. M. M. G., Chicago; age 41 years; admitted to Chicago Baptist Hospital Dec. 2, 1895; married eleven years, widow two years. Has had two children, the youngest 7 years of age. No miscarriages. Has not been well since the birth of last child. Menstruation very painful; leucorrhea profuse, excoriating and offensive; constant pain and bearing-down sensation in the pelvic region; exceedingly nervous; uterus enlarged; entire vaginal vault painful to the touch. Diagnosis, metritis with salpingitis. Operation, vaginal hysterectomy, Dec. 4, 1895. The patient made rapid progress and in ten days all nervous and digestive symptoms had disappeared. Dismissed, Jan. 6, 1896, cured.

Not a drop of alcoholic beverage was given to any of these patients neither before, during nor after the operation. Morphin was seldom administered, and then only in one-eighth grain doses with atropin hypodermically. The clamps were always removed

promptly at the expiration of forty-eight hours. Only once did hemorrhage follow this maneuver. This occurred in Case 21 and was easily controlled. Again, there was slight hemorrhage in Case 5 at the end of the second week. This was only slight, and I presume came from the vaginal wall while dressing the wound. One case, 19, developed slight parotiditis at the end of the second week but it subsided in a day or two. The temperature seldom reached above 101°. Once, in Case 18, it ascended rapidly on the third day to 105°, accompanied by great restlessness and delirium. After a vaginal douche of warm, sterilized water it soon resumed its normal course. At the usual time of menstruation the "menstrual storm" invariably made its appearance with a slight rise of temperature, but in no case were the symptoms very marked, and in no instance was there any appearance of menstrual flow.

My experience in vaginal hysterectomy leads me to believe that it has a much wider field for triumph in the future than was at first anticipated. I believe it will not only yield more satisfactory results to the honest surgeon, but that it will also spare many lives that might otherwise have been sacrificed to the more dangerous abdominal method.

240 Wabash Avenue.

HYSTERECTOMY, ITS LEGITIMACY, WHEN AND HOW.

REPORT OF A CASE INCLUDING REMOVAL OF FIBRO-CYSTIC MASS OF TUMORS, UTERUS, OVARIES, TUBES, PRECEDED BY LIGATION OF UTERINE ARTERIES.

BY R. E. HAUGHTON, M.D.

RICHMOND, IND.

Mrs. B. age 35 years, consulted me in regard to an abdominal growth and bad health as a result. So much so, it seemed that if she were not relieved soon she would not live long. It had been diagnosed an ovarian tumor and she was then as large or larger than at full term, and very burdensome. I examined her very carefully, took all the history and decided it was a cystic or fibro-cystic tumor and ought to be removed. The operation was a laparotomy and did not at first involve the idea of hysterectomy. Hence an exploratory incision was first made for completion of diagnosis. It presented the conditions and appearance of a multilocular ovarian tumor and was clearly a fluctuating one, but deviated in some particulars from the ordinary history of a simple ovarian cyst. First it developed centrally, while right or left ovarian cysts are found to begin in the right or left ovarian region, unless they are double, which is not usual. This led me to suspect I might find a fibroid or fibro-cystic development growing out from the body of the uterus. She had not menstruated for more than a year, the reason of which will appear in the sequel. This thought led me to an investigation of the possible condition, and relations of the uterus, but I was not able by any process, to find it nor reach it by any means of exploration adopted. I thought it had been lifted up out of the pelvis, and so it was found in the operation which took place for removal of growth. The tumor was both pelvic and abdominal, being a large tumor it had risen up out of the pelvis into the abdomen above the plane of the superior strait. She and her husband were fully advised as to its probable nature and the danger and risk of removal fully stated. I said to them in view of the rapid growth of late in the size of the tumor, that in consideration also of rapidly impairing health removal was the only thing left for them, beyond letting it alone and abiding consequences. They returned home saying they would decide as to the operation and notify me if it was for removal. Some days later, I was notified to go to their home and make the operation for removal.

The long laparotomy incision was made after a short exploratory one. The operation disclosed a large development of fibro-cystic tumors of various sizes from that of a child's head down to that of a small apple, growing out from about the neck of the uterus as a center and lifting the womb up and so compressing it that the usual examination failed to find it or determine where it was except that it was above. It had but a trace

left, in outline, yet sufficient to determine its structure and position. There were also almost universal adhesions to viscera and walls of abdomen, yet they could be readily detached as the operation progressed. Only about one-eighth to one-fourth of an inch of uterine structure in thickness remained. The tumor was movable and could be lifted up. The broad ligaments in sections and uterine arteries on either side were ligated close to the organ to secure them and thus prevent hemorrhage in the continuation of the operation. The broad ligaments were turned back laterally on each side like a cuff, after ligation of vessels and then after I had lifted up and forward the womb and tumor mass these lateral surfaces were united by suture, making an extra peritoneal finish of the operation. The operation of the vaginal neck was also next made by the supra-vaginal section. The ovaries and Fallopian tubes were also removed, as those appendages were shrunken or atrophied. Thus we had a removal of tumor, the uterus and its appendages included and were forced to this operation, more as it did not seem possible to have removed the tumor, except by the supra-pubic method. By ligation of uterine and ovarian arteries no hemorrhage occurred during the process, and the patient was placed in bed in a comfortable position with some depression: no bleeding at any joint. She rallied well and took some nourishment in the following morning, pulse fair, reaction good, doing fairly well quite comfortable, the morning of the second day. The external wound was closed by several interrupted sutures of silk and antiseptic compress and bandage. She began to show more depression second day in the evening, more rapid pulse, growing paleness of surface and death occurring on the third day, in the afternoon, from exhaustion as she was quite feeble and did not nourish well.

HISTORY OF FIBRO-CYSTIC TUMORS.

Whether the result could have been different in this case and others similar can only be determined by the study of the results of cases gone before, and also taking into consideration the late period of the operation in this case. Baker Brown says, he knows of no distinguishing signs between utero-fibro-cyst and ovarian cystoma. These have been recognized as a distinct class of tumors, and were first described by Cruveilhier. They have been frequently mistaken by the ovariologist for ovarian cysts. Where the growth has been rapid and fluctuation is very evident an error may readily occur. To make a more certain diagnosis an explorative incision may be made, yet in this case it did not throw any light upon the conditions, as even the hand in the abdominal cavity will not enable the operator to determine a fibro-cyst from an adherent ovarian cyst. Koberle says that the differential diagnosis ought to be clearly made, and Wells says that a darker and less pearly blue color of the tumor would be sufficient to put the surgeon on his guard against mistaking it for an ovarian cyst. Dr. Atlee admits the difficulty of diagnosis, and says that errors are frequent even in hard fibroid tumors, but are much more common in fibro-cystic tumors. He says further: "I believe that a positive diagnosis can be made only by tapping and testing the fluid by heat." "A fluid coagulable on exposure to air is, however, said to be the most reliable test." We find that so far medical men have not been able to make this differential diagnosis unless it be by this method of tapping and examination of the fluid, which enabled Atlee to determine correctly when others quite as celebrated as he had failed, as, for instance, Wells in a case presented to him for the purpose of diagnosis. For various reasons which seemed good this test was not made, as it did not seem so much a question of the kind of tumor as the more important question: Shall it be removed? Yet if there be a question of doubt at all in the comprehension of any or all questions coming before the surgeon it is right and best to use the means of skillful diagnosis, so that nothing be left undone which might cast a ray of light upon the clouded

sky of such a patient and reveal the true nature of her trouble. The question of the true nature of the tumor was raised in this case and fears entertained of its being a fibro-cystic tumor. Yet it was supposed that an exploratory incision would reveal its character rather than subject the patient to what has often proved a dangerous and fatal method of diagnosis, viz: tapping.

ESTIMATION.

I report this case because the conditions required a removal of the uterus and accessory organs, which were all involved in the widespread pathologic condition and because function was suspended, uterus and ovaries atrophied, menstruation stopped and the woman could not be more unsexed by removal than before, and finally, because it was apparent that if she could not be saved by an operation it could not be done at all. The tumor was a multilocular, fibro-cystic, of many and various sizes, from that of the size of an apple to a child's head of six months. Some of them contained fluid and some of them were solid fibroid tumors. They were arranged around the uterus as a center, springing out about the neck and body of the same, similar to a bunch of grapes or a cluster of hydatids which I once saw expelled from the uterus of large size, amid alarming hemorrhage. The entire weight after removal was forty-five pounds. Lastly, it was finally fatal on the third day, as I have stated from prostration, as I believe growing out of a long continued impaired nutrition during the history of the pathologic changes described in its development. Most likely the operative procedure added its modicum of influence as ultimate cause, but that the operation was correct in itself and successfully accomplished is a fact nevertheless now rendered certain. Lastly because it was a removal of uterus and accessory organs together with a large abdominal and pelvic growth somewhat unusual and out of the line of such cases, viz., atrophy of uterus and ovaries with consecutive arrest of function, where the removal of the growth necessarily required excision of all the organs involved.

HISTORY OF UTERINE REMOVAL.

Dr. Choppin, New Orleans (February, 1861), removed the uterus entire with one ovary and Fallopian tube and a portion of the other tube, leaving the other ovary. The woman recovered, being able to sit up on the third day. (*New Orleans Medical News and Hospital Gazette*.) Dr. Munde's (January, 1879, *American Journal of Obstetrics*) operation is described by Freund, of Breslau, with an illustrative cut, and which he calls a new method, an operation for complete removal of the uterus, in which the chief consideration is the prevention of hemorrhage and closure of the peritoneal defect. He does this by uniting the free peritoneal borders with the corresponding lateral portion of abdominal wound, thereby preventing the detachment of the anterior pelvic or abdominal peritoneum. His operations were made for cancer, of which at above date he had made ten operations; of this number only five have been published and five of the ten reported died (50 per cent.). I have referred to the modification proposed by Schroeder in Freund's operation, but as this is made for cancer of the body of the organ, and also involving the neck or mouth, one can thus make an incision which may cut clear of cancerous tissue

and by this means not complicate a possible recovery. In a case such as I have described, viz., the supra-vaginal incision is the only one that can or should be adopted if by that means the whole growth can be removed (I mean now a fibro-cystic or other tumor) by adopting it. In a paper on the surgical treatment of "Fibroid Tumors of the Uterus," of any variety involving the removal of the uterus recently, I discussed this matter more fully in comparison with others, showing that one of two methods may be resorted to, viz., laparotomy with the supra-vaginal section or the infra-vaginal method, if the tumor is not found too large; but if so found then the superior abdominal operation is the only one to be adopted if, provided, any operation is required and urgently demanded, as in the case here reported.

HEMORRHAGE AND ITS CONTROL.

This is one of the most important questions in such cases and up to the time of Martin's ligation of uterine vessels this method was not done, either for this purpose or for the limitation of blood supply to fibroid growths; and if one-sided ligation is not sufficient for such limitation of growth then double ligation may be done. In this operation of removal the double ligation may be used, securing control of hemorrhage in the after-steps of the operation. This ligation of vessels was done in case described, and when it had been made we had nothing but a vascular condition of tissue in which some bleeding occurred and this was easily controlled. One case is reported by Trenholme in which he used the ecraseur, and attributed the fatal result to it. This is a question which depends largely upon the conditions and circumstances which complicate the case, and the judgment of the surgeon.

HYSTERECTOMY, ITS LEGITIMACY.

Formerly, ten or twenty years ago, no question most likely would be raised in view of the cases which were reported as successful. Now, outside of exceptional cases, a halt may be called and the question comes back, what percentage of mortality occurs in the cases reported as a sum total. Moreover does the percentage of recovery justify such an operation, or to use a stronger term, mutilation? Before I proceed to give what seems to my mind legitimate indications for such an operation, I wish to go upon record as holding the opinion, carefully reached, that the tendency of surgical endeavor has been in the direction of too much surgery, too much cutting, and the mutilations, which I think express the idea, have occurred too often, and men have endeavored to carve their way to fame and distinction without the careful estimate which should be placed upon a human life standing in the social relations of wife, sister or mother. While I record this view, I am fully aware there are cases where there seems to be no alternative but an operation¹ or death, and this alternative should be accepted before it is too late, when vital force and power are almost gone and no resources are left for recuperation.² This is a critical question and it requires a knowledge of all the resources of surgical means as well as a comprehension of all the sources of vitality left to the patient. In

such cases as I am now describing the question of the sexual position of the patient does not enter; yet there are such cases as these where it becomes, as I regard it, a very important consideration. These questions come before surgeons at this juncture with more force than ever before, because of the considerations which arise along the line of treatment of many disorders peculiar to women, which have been more fully developed and outlined by Apostoli, of Paris. Others had preceded him, marking the way, but he has assumed a more commanding position. I refer to gynecologic electro-therapeutics. The difficulty has been that men have not comprehended the remedial power of the electric current, and have only applied it as a last resort, hoping it might do something more than had been done. In amenorrhea, dysmenorrhea, or pain so agonizing that it seems it might kill; endometritis and the discussion of fibroid tumors by electrolysis, also in hemorrhage, "where it has probably no equal in treatment," as Apostoli says. He uses the faradic current with the bipolar electrode in inflammation of the uterine and peri-uterine tissues, as metritis, para-metritis, salpingitis and salpingo-ovaritis, and even the most acute stage of disease does not contra-indicate employment of the current. Also the most severe local pain is much relieved either by the intra-uterine, bipolar electrode or the intra-vaginal, when the acute history has been passed. Apostoli assumes that 95 per cent. of his cases were improved and symptoms removed, while a fibroid tumor was not removed but rendered quiescent or latent. Dr. Thomas Keith, of London, in a paper June 8, 1889, says in regard to fibroids: "The only treatment not surgical worth consideration and free from danger is that of Apostoli." And after giving a history of the professional management by operation proceeds to say: "That hysterectomy, then, at best would appear to be a doubtful remedy for a certain class of cases, and these not the worst class of cases," viz., hemorrhagic cases. "The old spirit that at one time would have no abdominal surgery still lingers," and when other means than operative, "in the form of electrical currents are to be set aside as arrant quackery, and simply because they know nothing of its value." Another idea of those who operate most is this, that other surgeons who have made just as careful study and estimation as the specialist in surgery should not attempt an operation because he does not operate every day on some case, and hence is not so well advised. Away with the idea that one man may not minister at the altar of hygea as well as another. "Hysterectomy, which is performed every day for a disease that rarely of itself shortens life except by hemorrhage, kills every fourth or fifth woman subjected to it." This mortality is too much and should stop. "It is not surgery, it is humanity." Keith says: "I would give something to have back again those sixty-four women that I did 'hysterectomy' for, that I might make a trial of Apostoli's treatment upon them beside the wear and tear of flesh and spirit which those operations cost me, for in scarcely one of them was the operation simple." (*British Medical Journal*.) This operation may be performed when all other legitimate treatment has been used, as in cancer of the uterus, in sarcoma as well, when the disease has not invaded other organs, which would insure its recurrence if the patient survived the operation for removal; in fibroid and fibro-cystic tumors,

¹ I record my present view with the facts as given by Baldy and others, viz., Baldy, 31 cases, no deaths; Kelly, 70 cases, no deaths; Polk, 20 cases, 1 death; Pryor, 9 cases, no deaths; King, 65 cases, 1 death; Penrose, 25 cases, 1 death, making a total of 223 cases and 6 deaths. The mortality in the hands of six operators 1-2 per cent.

² So also we agree as to the success and percentage, but what about the health and condition in which the woman is left?

when by growth they have become distressing through pressure, pain and the consequences arising upon vital, thoracic or abdominal organs. Or when there is such a constant peritoneal irritation as to produce pain or adhesions; or when by hemorrhage likely to be sacrificed. One case in which I removed the tumor in time to prevent another hemorrhage and which must have caused death if the operation had not been performed, recovered well in about thirty days.

Dr Muller says, "that while ovariectomy has been brought to a high degree of perfection, the operation of hysterectomy has not yet passed the first stages of its development." Not only has the legitimacy of this operation been doubted and denied by experienced gynecologists, and while this question is being closely canvassed, the indications and contra-indications for a resort to it are gradually becoming settled. Nevertheless so much has been done, it is now claiming a place among the very grave surgical operations, which are not easily determined and may require a very careful exploratory incision and investigation before deciding that it shall be done and when it must be done in the careful judgment of the surgeon or surgeons, carefully weighing all the conditions; then they are not justly chargeable with temerity or cruelty in offering such relief, as only remains in this operation, with a percentage at best of mortality of one in five, or 20 per cent. This is the estimate of Thomas Keith, of London, and the adhesion of Sir Spencer Wells and Keith to Apostoli's methods of treatment, being among the world's most influential gynecologic surgeons, arrested the attention of all progressive and yet conscientious surgeons. While this is true, there are two factions of men, and all are not yet convinced of the efficacy of the galvanic treatment so ably defended by Apostoli, when he says that 95 per cent. of his cases were benefited, when not cured. I have written but suggestively, and here rest the subject for the present, hoping it may be like "a pebble cast into the ocean, its tiny wave may reach either shore" of professional opinion upon this subject.

CRIMINAL ABORTION.

BY WILLIAM McCOLLOM, M.D.

BROOKLYN, N. Y.

I use the words in their legal sense, viz, the effecting of the unlawful expulsion of the contents of the womb at any time after conception before the term of gestation is complete. The very old English law made a distinction between the crime perpetrated before and after quickening. The rulings of the supreme court of several of the American States corresponded with the old English law which was abolished a half century, more or less, ago. The Pennsylvania court was one of the first to discard the old doctrine and the courts of many of the other States have progressively fallen into line, and have ruled that it is a crime to destroy embryo life after gestation has begun. Judge Coulter, of Pennsylvania, ruled that "it is not the murder of a living child which constitutes the offence, but the destruction of gestation." An attempt by a physician or other person to procure an abortion is a crime, though the effort fail and the abortion is not produced, and it renders the party criminally guilty. When a physician prescribes medicine or gives advice and allows the patient or party to be-

lieve, or gives her reason for believing that it is given for the destruction of embryo life, though he does not intend such destruction, is little better than a criminal. I have heard physicians confess to such deception without seeming to realize that they were seriously compromising honesty and integrity and countenancing sin and crime.

Criminal abortion is frightfully prevalent and the practice is apparently on the increase among professed Christian women. It should be and it is the duty of the physician to enlighten applicants for relief from pregnancy who have no adequate idea of the criminality of the act. The women of the Church of Rome are better instructed and made to keenly feel the great sin of murdering unborn human life. I might raise the question whether the clergy are doing their duty in the matter or not, but I am addressing medical men only. Let us do our duty, if our spiritual advisers neglect to do theirs, in denouncing this common crime and great sin. It is evident that women of the lower class have no adequate idea of the criminality of the act, for they unblushingly apply to the physician and to the druggist for medicine to abort pregnancy, or, in other words, to bring about the monthly sickness. Great ignorance of the criminality of the practice is manifested by educated women, but it is not ignorance alone but a downright lack of moral sense as well, which greatly needs educating. The common law at the present day does not make the destruction of an unborn child murder. I quote Blackstone on English law: "Though to kill the fetus in utero is as such by common law no murder, yet if it be born alive and die subsequently to birth from wounds received in the womb, or from the means used to expel it, the offence becomes murder in those who cause or employ them." I also quote from another distinguished jurist, Wharton, "Law of Homicide," 93: "If a person intending to procure an abortion, does an act which causes the child to be born earlier than its natural time, and therefore in a state much less capable of living and it afterward die in consequence of such premature exposure, the person who by this misconduct brings the child into the world, and puts it into a situation in which it can not live, is guilty of murder, though no direct injury to the child is proved; and the mere existence of a possibility that something might have been done to prevent death, does not lessen the crime." We are inclined to the belief that such law is not good common sense; to kill the child in utero according to Blackstone is not murder or infanticide, but to inflict such injury upon it that though it is born alive and dies in consequence of the injury it is murder.

Some years ago I attended a woman, the wife of an attorney-at-law, seven months or more advanced in pregnancy, the child stillborn; the brain had been punctured through the eye from some instrument; this was not technically murder under common law, but I bluntly charged the mother with murder in the presence of her husband and friends, pointing out the evidence of it, and there was no denial. I have repeatedly been shocked at the manifest lack of moral sense in intelligent women in applying for medicine to reestablish the menstrual function when it was evident that they believed the absence of the menses due to pregnancy. The woman sometimes attempts to justify the act because she does not positively know that conception has taken place. The physi-

cian's excuse for giving noxious drugs or for sounding the womb when miscarriage results that he did not know that the suppression was due to pregnancy renders him not less criminally liable.

Under the older English law for an attempt to procure a criminal abortion without proof of the woman's pregnancy conviction could not take place. More recent rulings as well as amended laws now make the attempt to procure a miscarriage a crime. It has been the law of France for more than fifty years, that the proof of pregnancy is not essential to the commission of the crime. We try to excuse Christian women for asking us to terminate pregnancy on the ground of ignorance of the law of man, if not of the law of God. If they took as much pains to become enlightened in the common law regarding it as they do to how it can be accomplished with or without aid from others they would not long remain in ignorance in the matter. Physicians long in general practice know that the practice of criminal abortion is common, and that it is not confined to the laity or to the quack and the pretender. Sometimes the ordinary physician who may be a member of a regular medical society violates his duty; and the distinguished college professor without the fear of God or of sufficient fear of human law takes his large fee for the criminal act. I am not drawing on the imagination, but state what I know to be true. Such statement does not sound well, but this fearful immoral destructive practice can not be checked unless facts are stated and proclamation is made of this great evil.

I have no belief that the practice is common among physicians who have a reputable standing with the profession in the neighborhoods where they are known. The moral status of physicians is high and I trust that we have no more black sheep than the other learned professions. As we go down the scale from the higher to the lower the evil grows greater, until the criminal abortionist, who may be a graduate of a regular medical college, loses all shame and not only sends out his advertisements to the laity, but his cards at frequent intervals to reputable physicians as well. These villains would not continue to inform the medical profession at considerable expense to themselves year after year unless their business was helped by it. A little lower down in intelligence, if not in wickedness, comes the so-called midwife and the woman who prefixes doctor to her name, and poses as a dermatologist or specialist in disease of females; they flourish in many localities.

Now we come to the economical woman and her economical friend, with their skewers, steel knitting needles and other instruments of murder. Quite recently an intelligent, educated professed Christian woman whom I attended in a miscarriage in the fourth month of pregnancy, confessed without expression of sorrow or remorse that she had effected the abortion with her own hand by pushing a knitting needle into the womb, following the instruction of another young woman who had repeatedly succeeded in destroying embryo life in her own person and was kindly instructing her young friends in the art without hope of pecuniary reward. It is only necessary for me to briefly call attention to the existing criminal facts, for all physicians who have had full opportunity to observe know that the alleged statements are true, and not overdrawn; true of the city and true of the country.

Much might be said of the far-reaching, demoralizing destructive influence upon woman, upon the community, upon the State, upon the world; but the portraiture of the facts, bad as they would appear, I fear would have little influence in arresting the practice. The moral sense in woman, and possibly in the medical profession as well, has degenerated as regards this matter. The physician is so related to woman in his professional duties that he can do much, if he will, to instruct her as to the law and to show her that she would be a criminal, and shock her into a sense of her duty. It is presumed that few people know that the penal code of many of the States make the woman guilty of manslaughter if she consents to the procuring of a miscarriage. I quote from section 194, New York penal code: "A woman quick with child, who takes, or uses, or submits to the use of any drug, medicine or substance, or any instrument or other means, with intent to procure her own miscarriage, unless the same is necessary to preserve her own life or that of the child whereof she is pregnant, if the death of such child is thereby produced, is guilty of manslaughter in the second degree."

When one woman advises another woman to procure an abortion, instructs her as to the method or assists her in any way in its performance, she becomes a criminal and is guilty of manslaughter.

Section 191, Penal Code of New York, says: "A person who provides, supplies or administers to a woman, whether pregnant or not, or who prescribes for or advises or procures a woman to take any medicine, drug or substance, or who uses or employs, or causes to be used or employed, any instrument or other means, with intent to procure the miscarriage of a woman, unless the same is necessary to preserve her life, in case of the death of the woman or of any quick child of which she is pregnant is thereby produced, is guilty of manslaughter in the first degree."

The field for missionary work is a large one and should be faithfully worked, both by the conscientious physician as well as by the Protestant Christian clergy, who perhaps fully understand the enormity of the sin if they do not know how prevalent it is. It is not a pleasant subject to discuss before a mixed audience. Young women could be reached, instructed and warned by a properly published circular or tract sent to them by Christian organizations at intervals, where personal instruction would not be practicable. There is little to criticize, as it relates to the laws of most of the older and some of the newer States of America. A recent ruling, June, 1895, by the supreme court of Kansas, rendering an important section of the Crimes Act as it relates to criminal abortion invalid, is a long step of about fifty years backward. The law provides that an attempt on the part of any one to abort "any woman pregnant with a quick child" "shall be guilty of manslaughter in the second degree;" this is declared inoperative and invalid "where neither the death of the child nor the mother results from the acts committed." The low moral sense of the community, as it relates to the offence, has much to do in the non-enforcement of the law. The criminal is seldom put under arrest unless the woman is murdered, and then the party, if convicted, frequently gets the minimum penalty prescribed by law. If physicians would do their duty and make complaint in all cases when it comes to their knowledge that physicians or other persons are violating

the law in the destruction of unborn human life, it would do much to lessen the practice. I have more than once made written appeal accompanied with a threat that unless I could be satisfied that the practice would stop, I would enter formal complaint to the legal authorities. Parties have responded, pleaded for mercy and given solemn promise never to again produce the miscarriage of a pregnant woman for any reason until they had held a consultation with a reputable physician, and its necessity was advised. It is not safe or best that any doctor procure the miscarriage of a woman in case of necessity until a consultation with another physician is had; such practice would protect himself against suspicion of wrong-doing, and materially help to trace and convict the criminal. So long as it is allowed the physician to produce the miscarriage or the abortion of a woman without consultation the evil will not be materially checked, for the criminal abortionist is a perjurer and when under trial in court will swear if necessary to avoid conviction, that the act was performed to prevent the death of the woman from disease, pelvic deformity, or for some reason given, satisfactory to the jury. It is very easy to speak upon this shocking criminality practiced by professed Protestant Christian men and women, as well as by the ungodly, and to moralize upon the destructive influence, especially upon woman, but it is difficult to solve the question when we ask, What is the remedy? How can it be checked?

CASES ILLUSTRATIVE OF DIFFERENT FORMS OF COLOR-BLINDNESS.

CASE I.—CONGENITAL COLOR-BLINDNESS.

CASE II.—TOBACCO COLOR-BLINDNESS.

CASE III.—TRAUMATIC COLOR-BLINDNESS.

A Clinical lecture delivered before the Senior Class at the Jefferson Medical College, Philadelphia, April 5, 1895.

BY WILLIAM THOMSON, M.D.

PROFESSOR OF OPHTHALMOLOGY IN THE JEFFERSON MEDICAL COLLEGE;
OPHTHALMIC SURGEON TO THE PENNSYLVANIA RAILROAD, ETC.

[Reported stenographically for the JOURNAL.]

Gentlemen:—Your Clinical Professor of Ophthalmology has invited me to address you on the subject of color-blindness. I must suppose that you have been made acquainted with the anatomy and physiology of the eye, by the teaching of my friend and colleague, Professor Hansell, who is so well qualified to instruct you upon this subject. Taking, therefore, your familiarity with these preliminary matters for granted, I will proceed at once to tell you what is meant by color blindness; and how the condition may be recognized. I will also explain the tests, and give you clinical illustration of their application. In this way, you will get a practical demonstration of the methods of examining patients who are suspected of having a defective color sense.

When we speak of congenital color-blindness, we mean that the eye may be perfectly normal in its structure, have no anomaly of refraction, and be a perfect optical instrument, except for one defect, and that is the inability to distinguish the difference between colors, which to ordinary, normal eyes is very obvious, such as red and green. It is precisely these colors, however, which have been selected for signals on the railroads and on shipboard, where failure to recognize them may cause serious loss of life and property. You will appreciate this better when I tell you that there are cases of total color-

blindness in which the solar spectrum looks to the patient like a lead-pencil drawing of it; where, from red to indigo, the spectrum looks as if drawn in different shades of gray. Such cases, however, of total color-blindness are rare; indeed, I have never met with a case of this kind. On the other hand, cases of partial color blindness are common. For instance, there is blue, yellow, red, and green blindness. What is most commonly meant, at the present day, by color blindness, on account of its wide-spread and far-reaching consequences, is the inability to distinguish between red and green, or green and gray. When you realize that the individual presenting this defect to the examiner would show the same in ability to distinguish between red and green flags or lights, which are commonly used as signals at sea or on railroads, you will understand the great importance of testing the eyes of all pilots, and of engineers and brakemen particularly. The correct interpretation of those signals depends upon the ability of the engineer or lookout to recognize certain colors at sight. The white light or flag on the railroad means: "Go ahead;" the green, "Proceed with caution;" the blue, "Do not move it;" but the red light or flag means imperatively, "Halt." It is important to recognize lights at sea, for another reason, because by their aid the course is indicated in which a ship is sailing. The red light is hung at the port and the green at starboard, with a white light on the mast-head. By the relative positions of these lights the direction may be known. In the recent calamity by which the steamship *Elbe* was injured in a collision in the North Sea and foundered with all on board, I am not sure that it was not due to the defect in vision of which I speak to-day. The accident occurred at night when there was no storm, and the atmosphere was clear enough for ships to see each other for a long distance before they met. It might have been due to the fact that the lookout on the *Craithie* could not tell which way the *Elbe* was going, owing to color-blindness, which prevented him from correctly interpreting the signals on the *Elbe*. So, you see that this is a matter of very great importance, especially to all of us who may have occasion to travel by land or water.

Now, we will see if we can approach this subject in some way so that you will get a clear idea of the color sense and of the relations of colors. Here, on this plate I show you a colored representation of what is commonly known as a "spectrum" "or solar spectrum." This teaches you that if you go into a dark room and make a small hole in a shutter, that the beam of light (or if passed through a prism) will break up into this arrangement of colors upon a screen, with blue light at one end and red light at the other, as everybody knows. The reason why the spectrum is formed is because a beam of white light is made up of a number of rays having different wave lengths, or rates of vibrations. Thus, the red rays at one end of the spectrum have about four hundred million millions of vibrations per second, while the violet at the other end have over seven hundred and fifty million millions. All rays under four hundred billions of vibrations per second are not perceptible as light and are known as heat rays, while those higher than the violet can not be appreciated by the human eye and are only recognized by their chemic and physical effects. Between these extremes of red and violet are found the orange, yellow, green and blue rays with

rates of vibration of four to eight billions per second.

You may ask why it is we see only a small portion of the spectrum, and that the higher and lower rays are not luminous. It is because the human eye has been evolved from lower forms of animal life, and its condition is the result of the action of external forces of nature upon it during the course of its development to fulfill the needs of the human organism. We will suppose that the light falls upon the cornea and passed through the crystalline lens and that impact takes place upon the retina. A commotion is set up among its rods and cones, the red rays and violet rays make a different impression upon the nerve endings in the cones, and this is carried backward through the optic chiasm to the part of the brain which we have ascertained, by pathologic and other observations, to be the center for vision, which is situated in the occipital lobe of the brain in the cuneus. From here it is carried on to consciousness, and if any of you, gentleman, can tell me where that is and how these impressions become conscious sensations, I shall be very much obliged to you for the information. Having traced the impression to the cortical center in the occipital lobe, there we must leave it for the present; all we know is that it is carried to the cuneus and thereafter it becomes to us conscious sensation.

Case 1. Congenital Color-Blindness. Now, gentlemen, I will show you this case of color-blindness, in order to demonstrate the nature of this phenomenon to you. I will first give him fine print to read and thus test each of his eyes, to prove to you that they are perfect as optical instruments, and that vision is acute and accommodation normal. He says that he first learned that he was color-blind when he bought what he thought was a blue necktie, and when he brought it home he was laughed at for buying a green one. This led to conversations upon colors, which showed him there were differences recognized by others, but which he could not appreciate.

It is of interest to mention that it is to Dalton, who was himself afflicted in this way, and who a hundred years ago was a distinguished professor of chemistry, that we owe our first exact views on the subject of color-blindness. He also ascertained the peculiarity by accident. He was living at Oxford, and when he went up to take his degree he was informed that he must wear a red coat, and it being against the rule of the religious society to which he belonged, he was much troubled about it. When the coat was brought home, he thought that they had changed it for a mouse-color or drab and he was very much pleased with the shade. He thought so well of it that he not only wore it to the ceremony when he received his degree, but he also wore it in the street until his friends spoke to him about it, when he learned for the first time that the coat was red. He investigated this subject and taught the use of the spectroscope in diagnosis. After Dalton came Dr. Thomas Young, who made observations upon the color sense, which have become classic. Now, coming down to our own time, Holmgren taught us that color blindness was comparatively common among the railway employes in Sweden, and devised a very practical test for the examination of their color sense.

Now, let us suppose that you will be called upon to examine a suspected case. It will be useless to ask him to name colors, for he has learned to apply these names which he will use in speaking, although he could not distinguish the green from the red, perhaps except by a slight difference of shade, both appearing as dark gray. Now, according to the doctrine of probabilities, if you take a large number of men, you will find that 1 man out every 100 will not be able to distinguish between red and green, or will be color blind; whereas there are only about 4 women out of 6,000 who are color blind. This would really show on this point a superiority of the female sex, in the ratio of 1 in 25, in males, to 1 in 1,500 females possessing this defect of color-blindness.

We will now proceed to the test for color blindness. The best way to ascertain the existence of this condition is to ask the subject of the test to match certain colors. Here is a mass of over a hundred small bundles of wool of different shades of green, pink, blue, orange, etc. In making then, what is known as Holmgren's test, three test colors, viz., light green, rose or purple, and red are placed in turn before the person to be ex-

amined, and he is told to select from the mass a number of skeins and to sort them according to the color.

This test will now be made upon our patient. Observe that he takes a rose-pink and lays upon it the light blues and hesitates about the grays. In assorting the colors, as requested, you can see, without asking him any questions, that he is unable to distinguish between certain colors, and especially green and red, and makes ludicrous mismatches. He reminds me of a young man who happened to be color-blind, and who describing his ladylove said that her cheeks (pink) were the same color as the sky (blue). I have no doubt that there are a number of gentlemen in this class who are color-blind, and if so, they should know it, in order that they may avoid errors and thus succeed in their professional lives. There are many things that appear differently to the color-blind physician, and we often depend upon full appreciation of color for our diagnoses. For instance, a rash upon the skin would not look the same to such an individual as to others with a normal color-sense. Chemic tests, dependent upon color changes, would be rendered uncertain and difficult to a color-blind doctor.

Here is a bundle of skeins of wool of neutral colors which our patient selects. Here is a pink, which this man calls a dirty white. If he were an engineer and should make such a mistake confusing a red with a dirty white flag, the results might be serious. Now, if we confront this man with the picture of the spectrum, we find that he can distinguish blue and yellow better than red or green. Therefore, if we divide the spectrum into four colors, red, yellow, green and blue, he can distinguish yellow and blue well and fails on the other two colors, and he has hence that form known as red-green color blindness.

Some difficulty arises owing to the partial education of the color-sense in these cases, so that we can not ask them to name the colors, or to select colors by name. But we must ask him to match skeins of worsted by placing him before this box filled with many colors, from which he must select those corresponding in color to the test skeins, but lighter or darker in shade.

The rose-pink, as you may know, is a mixture of red and blue. Therefore if he matches this with a blue, he is red blind; and if he matches it with green or gray, he is green blind. Now, you see he gives himself away in two ways; he not only matches the rose-pink with a blue, but fails to pick out the other pinks in the mass right before him. He then picks out a bright red and throws it upon the green test. This shows that his eye is incapable of responding to the four hundred million millions of vibrations in a second, which correspond with the red color. Now, if he were a doctor, and were to examine the eye-ground with the ophthalmoscope, the field would look to him as if bright green or dark yellow.

One other point should be mentioned. Nature is very miserly in her gifts and, while our color-sense is most acute in the very center of the posterior segment of the retina, outside of this portion of the retina we are all relatively color-blind. The response to the color rays becomes less decided as we pass from the center to the periphery of the field of vision in normal eyes.

As our color-blind subject sees in the spectrum only blue and yellow, he has a dichromatic color-sense, that is to say, a color-sense limited to two color sensations only. The normal sense is trichromatic: red, green and violet, which are the three color sensations necessary to produce white light. If this man should attempt to paint the solar spectrum, he would place blue at one end and yellow at the other end, with a neutral gray band between, as he has only two color perceptions. His entire color scheme of nature most correspond to this fact, and would necessarily be very different from that of other persons who have all three sensations. Therefore, his appreciation of nature is much more limited than that of those with full perceptions of color. He would not be able to pick strawberries out of a patch, or cherries from a tree, except by the form of the fruit; and in his eyes a red rose would not be very different in color from its leaves.

This examination which I have made by Holmgren's test can be very much facilitated and shortened by that instrument known as "the color stick," which was invented by me in 1879, for testing the employes of the Pennsylvania Railroad. The simplicity of this instrument and the positive character of the results, make it valuable also for preserving records, and it has the great advantage that the test can be made with it by laymen and non-professional people. I think that it is always better to have a trained surgeon to supervise the examinations; but at the time that this system was introduced it was impossible to find a sufficient number of ophthalmic surgeons to supply the demands of the Pennsylvania Railroad, where there were about forty thousand men in the employment of the company, scattered over thousands of miles of railroad. To accomplish this result, I devised this instrument. It consists of

forty skeins of worsted, arranged in a single row, upon two sticks joined together, but which can be taken apart. Each skein has a ring and a little bangle upon which is stamped its number. Twenty of these skeins are affirmative and twenty are negative; all the affirmative bear odd numbers, all the negatives are *confusion colors* and have even numbers. Now, if a person's color-sense is normal, he will select all the odd numbers, while the color-blind person will select a portion of the even numbers. As each skein is selected, it is turned backward so as to hang over the top of the stick. At the end of the examination the results are read off and entered upon a printed blank form, which is then sent to the superintendent, who can tell at a glance whether the man is or is not deficient in color-sense, by an inspection of his odd or even numbers.

Now we will give this man a skein of green to hold in his hand and he is told to pick up some others from the stick that look like it. Observe, now, that the even-numbered skeins show his mistakes. He is now given a rose-pink and told to pick out skeins to match it. The former test is confirmed by his selection again of even-numbered skeins. The result is read off immediately and recorded on the blank, and color-blindness is the diagnosis.

The new system recently adopted by the Pennsylvania Railroad is the following: The stick has been discarded and the test consists of two different sets of worsted skeins which must always be kept apart, not only in their corresponding parts of this box, but also in testing the men. The first set consists of twenty skeins, numbered 1 to 20 on bangles, these numbers being so concealed that the men can not see them. Among these numbers the odd ones (1, 3, 5, etc.) are greens, while the even numbers (2, 4, 6, etc.) are grays or light browns. The second set consists also of twenty skeins, but they are numbered from 21 to 40. Here the odd numbers (21, 23, 25, etc.) are all different shades of rose color, while the ten even numbers (22, 24, 26, etc.) consists of four blues, three greens and three grays.

The following directions are to be observed in the use of this test:

1. Examine only *one* eye at a time, by covering the other eye with a handkerchief or some other means, that will exclude it from vision.
2. Spread a white cloth, like a towel, on a table in a good light.
3. Take out all the worsteds from the green part of the box and put them on the cloth at random.
4. Take from this heap the large light green test skein which is marked A, and laying it to the side in a good light direct your man to select ten skeins from the heap. Tell him that they are not to be exactly like it in every respect, but that they are to be of the same color, only a little lighter or darker in shade.
5. Write down on your blank the numbers of the ten skeins selected by your man to match the test skein A. If only odd numbers appear which he selected promptly, then he is not color-blind; but if even numbers have been chosen, he must be more or less color-blind.
6. Ask him the name of the color he has been matching, or any other worsted, and register his answer on the blank.
7. Remove now all the worsteds and put them back in the green part of the box.
8. Now take out the second test and expose it on the table in the same way as before.
9. Show him the large rose-colored test skein, marked B, and ask him to match this with ten worsted in the same sense as before the first test.
10. Register his ten selections on the blank. Now any even numbers selected betray and determine definitely his color-blindness. If your man selects *blues*, with the test skein B, he is *red-blind*; if he selects *grays* or *greens*, he is *green-blind*.
11. Ask him the name of the test skein, or any other skein, and register it.
12. Put down whether his selection was prompt or hesitating.
13. Finally, as a control upon the test and as a substitute for the second and third color-test of the old system, there have been arranged especially for the surgical expert, two more large test skeins, one *c*, yellow, and the other *d*, blue. The test *c* is exposed and you ask your man to match it, if possible, by the skeins from 1 to 20. If normal in color-sense, he will decline or at the most only take the yellow-green skein, but if color-blind he will select a number of the green skeins, which should be recorded. Then use test *d*, the blue skein, and let him match it from skeins 21 to 40. If normal or green blind he will select blues only, but if red blind he will pick out a series of roses, which should be recorded.

The old system is now in actual use by more than forty of the principal railway corporations in this country and Europe,

and over fifty-two thousand miles of railroad are now protected by it. It is used not only for those actually in service of the railroads, but also for all applicants who seek such employment. To make the examination of vision complete, records are also kept of the results after testing by Snellen's test types for sight and power of accommodation.

In Holmgren's test as originally conducted, the examination took considerable time and required an accurate knowledge of the subject on the part of the examiner. By this system of mine, the tests are quickly made and recorded, and the results are equally positive.

Now, gentlemen, I think that you are satisfied that I have exhibited to you a typical case of marked congenital color-blindness. This was probably inherited either from his father or grandfather, possibly from his maternal grandfather, since, as already mentioned, the females usually escape color-blindness. I think, moreover, that you would not like to ride in a train behind a locomotive in charge of this man as engineer, who would then be called upon to recognize all kinds of signals at a glance by night as well as by day, when as he has just told you he sees green as dirty white, and red is indistinguishable from green.

There is another easy test known as the cobalt blue test, which I will demonstrate to you. A lighted candle is held about ten feet from the patient and a piece of cobalt blue glass is held before each eye in succession, the other being closed. Now to the normal eye, the flame of the candle should be pink or rose surrounded by a blue halo, but this man tells us that he sees only one color which he calls blue, and thus demonstrates his inability to see any red color, since this glass transmits both red and blue rays.

Case 2. Acquired Color-Blindness of Toxic Origin. I will now refer to this other case in which the color-blindness instead of being inherited has been acquired. This man for twenty years has used tobacco to excess, and he has, as the result, a central scotoma, or partial loss of vision with color-blindness over a limited area of the retina, involving the yellow spot, which is the center of most acute vision. In this large colored plate of the eye-ground, I now show you a very fine delineation of what we see at the back part of the healthy eye by the aid of the ophthalmoscope. Here is the optic disc or the entrance of the optic nerve, and here is the yellow spot, about 8 degrees to the outer side of the disc. Immediately at this point is the *fovea*, the seat of most acute vision and likewise of the highest development of the color-sense. When a man has any lesion in this region, it reduces his appreciation of both color and form very materially, if not totally. Outside of this central region everybody is relatively color-blind, the periphery of the retina being less responsive to color vibration than the center.

To prove to you the color defect, I take this red glass from the test case and place it in front of a lighted candle at six feet away; now by replacing it with green we find him unable to distinguish between green and red. I now measure the diameter of the test glass and find it 33 mm. I now bring the candle to 33 cm. (or thirteen inches) from his eye and he begins to feel the red color of the glass, and distinguishes it quite promptly if the lighted candle is moved a little from its position. When it is removed farther from the eye he is color-blind, but when it is approached, say to 25 cm. (or ten inches) he at once perceives either red or green colors, properly. Now, at 33 cm. this stick in my hand, of 33 cm. in length, covers 60 degrees of his retinal surface; the red or green glass is 33 mm. or one-tenth the size, and hence covers 6 degrees of his retina; and as he is color-blind for an object of this size, we are able to prove that within 6 degrees at his fovea he is color-blind, but if a larger portion of the retina is covered by the image of the test, it responds in a normal manner. From this, you will infer that this man would be incapable of seeing the signal-lights at night and would mistake red for green, or white for green, but that he would escape detection perhaps if tested by any colored wools, since each skein would form an *image* of more than 6 degrees upon his retinal center, and would touch rods and cones with normal sensation. Such cases are rare, and should be remembered by those who have the charge of lookouts on the water, or on railways on land. Accidents, alcohol, some of the fevers, may cause this condition and would render re-examination of suspected men necessary even after they had once passed the color-blind examination.

This, then, is a case of acquired color-blindness with central scotoma only, due to excessive use of tobacco; and it differs from the preceding case in being amenable to treatment by tonics, such as strychnin, etc.

¹ This man recovered his full sight both for form and color under disuse of tobacco, and internal use of strychnia. His color scotoma extended for 6° and involved the central or macular band of nerve fibers only.

Case 3. Traumatic Color-Blindness. I have another case to show you but the termination of the hour will permit me only to advert to it very briefly. This patient sustained a severe injury some months ago. He fell down twenty or thirty feet into an elevator shaft and suffered a concussion of the brain. At this time he probably sustained a lesion of the cuneus in the cortex of the occipital lobe of the right hemisphere. It was ascertained recently that he has hemianopsia for color only. One-half his field of vision in each eye, is color-blind, while he has a perfect appreciation of color and form in the other half.

I show him to you as a case of traumatic color-blindness limited to one-half of each eye, following an injury to the occipital region. I am indebted to Dr. A. G. Thomson for this case.

With this case, I conclude the clinical remarks I wished to make upon these three patients, which will illustrate the congenital, the acquired and the traumatized forms of this very interesting and very important condition of so-called color-blindness.

HYSTERIC BLINDNESS AND PSEUDO-MENINGITIS, WITH REPORT OF A CASE TREATED BY HYPNOTISM. BY HUGH T. PATRICK, M.D.

PROFESSOR OF NEUROLOGY IN THE CHICAGO POLICLINIC; INSTRUCTOR IN CLINICAL NEUROLOGY, NORTHWESTERN UNIVERSITY MEDICAL SCHOOL; CONSULTING NEUROLOGIST TO THE ILLINOIS EASTERN HOSPITAL FOR THE INSANE; ETC.
CHICAGO.

Hysteric amblyopia with contracted visual field and dyschromatopsia is common, monocular amaurosis is less common and hysteric total blindness is rare. Gilles de la Tourette in his recent work¹ refers to only eight cases as already published, viz., Landouzy, two cases;² Briquet, three cases;³ Marlowe,⁴ Würdeman⁵ and Levy,⁶ each one case; and in looking up the references I find that the case of Würdeman is not a case in point, but one of hysteric deafness. To these I have been able to add fourteen more from the literature beside my own. Harlan⁷ refers to a case cured by the application of an imaginary magnet and to another which occurred in the practice of Dr. Agnew. Jeaffreson,⁸ two cases; Moore⁹ mentions a case occurring in the practice of a colleague. Brown,¹⁰ one case, although it is not reported as one of hysteric blindness; Buzzard,¹¹ one case; but it is not stated positively that the amaurosis was complete. Dujardin-Beaumetz and Abadie,¹² Thompson,¹³ Mendel,¹⁴ and Oppenheim,¹⁵ each one case, the latter's patient having had thirteen attacks in ten years, one of them lasting a year and a half. Gowers¹⁶ reports a case in which there were several transient attacks. I have included in this category two cases reported by Barkan,¹⁷ although in each instance a careful examination revealed perception of light on one side. Since the foregoing was written Mitchell has reported a case.¹⁸ A more extended search would possibly bring additional cases to light, especially from the older literature cases recorded as simulated blindness and malin-

gering, for prior to the investigations of the French school these cases were not generally understood, and even now there are physicians who can not, or at least do not, distinguish between patients who see but who do not know it, and those who see but will not tell it. But in considering the cases we have only to remember that hysteric amaurosis is simply an hysteric anesthesia, produced by the same processes and amenable to the same laws as other hysteric anesthetics. There is no essential difference between monocular blindness with binocular vision and total anesthesia of the hand which still allows the patient to tie a bow beneath her chin with unimpaired dexterity. Some of the older cases of "reflex blindness" from slight injury of the eye or from irritation of the fifth nerve were doubtless hysteric.¹⁹

The diagnosis of hysteric blindness is usually not difficult if the physician simply bear in mind the possibility of its occurrence and have a fair knowledge of the symptomatology of hysteria. What may be called the negative symptoms are first to be considered. The pupils are ordinarily normal, the fundi oculi are normal as are also the cranial nerves; the corneal and lachrymal reflexes are present and the interrupted galvanic current causes flashes of light as in a normal eye; but it must not be forgotten that exceptions have been noted to all these rules. In Mendel's case the pupils sometimes responded to light and sometimes were fixed; one of Harlan's cases had rigid pupils as did also that of Dujardin-Beaumetz and Abadie, and in Levy's and one of Barkan's cases they reacted sluggishly. In Levy's case also the corneal reflex was lost and the eyes turned upward and to the left, and in one of Jeaffreson's cases there was no light-reflex to the galvanic current. The fact that the blindness is not due to changes in the intra-ocular structures does not preclude the fortuitous presence of such changes; for instance, Gilles de la Tourette alludes to a case with syphilitic choroiditis. Hysteric strabismus, ptosis, facial paralysis and deviation of the tongue have been observed and there is nothing to exclude the possibility of any one of these complicating hysteric blindness. Donath,²⁰ in a case of hysteria under observation for four months, found that sometimes one pupil, sometimes the other did not respond to light and this was accompanied by paralysis of accommodation, but there was no amaurosis. S. Weir Mitchell²¹ reports a peculiar instance of hysteric amblyopia almost reaching amaurosis in which the pupils reacted sluggishly and at times that of either eye only to light let fall upon the retina of the opposite eye. In making the diagnosis it is to be remembered that a lesion of the brain may cause total blindness with normal pupils and fundi if the focus of disease be bilateral, situated posterior to the corpora quadrigemina, and large enough to destroy the visual centers or cut the optic radiations on both sides; but a lesion of such magnitude whether due to hemorrhage, softening, inflammation, abscess or a new growth would cause other and marked concomitant symptoms, and therefore another necessary negative symptom of hysteric amaurosis would be the absence of other signs of such a lesion. The positive symptoms to be considered would be those of hysteria but I shall stop at the barest mention of the principal ones. Anesthesia,

hyperesthesia, monoplegia, hemiplegia, paraplegia, contracture, tremor, chorea, stuttering and other affections of speech, disturbance of the special senses, convulsions and the general mental state, any of these bearing the characteristics known to belong to hysteria; vaso-motor phenomena, loss of pharyngeal reflex, and especially anesthesia of the conjunctiva and eyelids are to be mentioned and always sought for. The mode of onset might be of diagnostic worth; blindness coming on suddenly after great psychic disturbance or gradually as a concentric and increasing contraction of the field of vision with dyschromatopsia, or following an etiologic factor sufficient for auto-suggestion but inadequate to produce blindness otherwise, as a slight traumatism, atropin dropped into the eye or association with a blind person, would indicate the hysterical nature of the affection. But hysterical amaurosis may come on without ascertainable cause (possibly during the night) in a person who has never shown any signs of hysteria and who is found to bear none of the stigmata; that is, the case may be an example of primary, or initial, mono-symptomatic hysteria. We must then depend entirely upon the negative signs and it is particularly in these cases that hypnotism may come to our aid in diagnosis as in treatment. Hysterical blindness is to be differentiated from that of exhaustion or anemia and if it follow an injury, especially in the vicinity of the eye, with profuse hemorrhage, the diagnosis might at first be difficult. Neither is the hysterical affection to be confused with the blindness of ophthalmic migraine, that is, migraine with marked disturbances of vision. These consist ordinarily of scintillating or central scotoma, amblyopia, or hemianopia not infrequently accompanied by disturbances of speech. There may also be visual hallucinations or transient blindness. Charcot and Babinski²² have attempted to show that this affection is sometimes hysterical but, however that may be, the blindness is totally distinct from hysterical blindness. We might have an hysterical ophthalmic migraine accompanied by an amaurosis that could not be called hysterical, and we might have an hysterical amaurosis following a migraine not in the least hysterical. The pathology of the two affections is entirely different. The one is of purely psychic origin, the other due to a disturbance, probably circulatory, of the visual centers. There is another psychic blindness that is to be distinguished from the hysterical, although the lines of division may blend in individual cases. This I am tempted to call the blindness of insanity and is simply a delusion entirely comparable to the ordinary delusions of the psychoses. These cases again shade off into those of photophobia, blepharospasm, etc., in which the patient fears the light, can scarcely open the eyes, may believe that he is blind but can see if he can be made to look.

Hysterical pseudo-meningitis, a knowledge of which we owe almost entirely to our French confrères, was first described as such in 1873 independently by Arnozan²³ and Saint-Ange,²⁴ although Briquet fifteen years previously had written of hysterical headache accompanied by chills, vomiting and sometimes fever. The principal later contributions have been by Dalché,²⁵ Chantemesse,²⁶ Macé,²⁷ Pitres,²⁸ Bardol,²⁹

and Brugère,³⁰ although a number of cases have been reported by other observers in France, Germany and England; none, so far as I know, in this country. I shall give here but the briefest résumé of the subject and pass rapidly to the report of my case which is, I believe, unique in showing the combination of this symptom-complex with hysterical amaurosis.

Hysteria may present a clinical picture so similar to acute or subacute meningitis as, for a time, to make a correct diagnosis impossible. There may be constant headache, vomiting, retracted abdomen, rigidity of the spine, opisthotonos, double vision, great prostration and mental hebetude, delirium or somnolence, retention or incontinence of urine, convulsions, with fever and rapid or subnormal pulse. Furthermore, the vomiting of hysteria is like that of meningitis, spasmodic, projectile, generally without nausea or gastric pain. The fever of meningitis is ordinarily moderate and irregular or rapidly fluctuating; the same may be said of that of hysteria. In hysterical pseudo-meningitis temperatures of 101, 101.5, 101.8, 102.5 and 103.1 degrees F., have been observed and a pulse-rate as low as 48. The diagnosis must generally be made by means of other symptoms of hysteria (as indicated in connection with hysterical amaurosis) although in some cases the entire absence of fever and abnormality of the pulse indicate the character of the affection. In most instances a careful search has revealed hysterical stigmata. In Charcot's case a rhythmic chorea at once gave the clew. In one of Guignon's cases it was the general conduct of the patient that indicated the nature of the malady. Occasionally only the sudden recovery of the patient has changed the diagnosis to hysteria. In one case Chantemesse demonstrated an inversion of the ratio of the urinary phosphates, such as was found by Gilles de la Tourette and Cathelineau³¹ to be characteristic of an hysterical attack. As Gowers has pointed out, the strabismus of hysteria is nearly always convergent, of both eyes and spasmodic, while that of meningitis is paralytic and not equally convergent on both sides from the first. In the hysterical affection with pain in the head a hysterogenic zone may at times be found on the scalp. In a doubtful case where the question of tubercular meningitis is to be considered the tuberculin test for tuberculosis might be tried or tapping the spinal canal with examination of the fluid for bacilli. The pupils are generally and the fundi oculi always normal, but these signs are of small negative value. The pulse in the hysterical affection may be rapid, normal or slow, but has never been observed to be irregular. Indeed as there is no pathognomonic symptom of meningitis and no one symptom is necessary to make the diagnosis, neither the presence nor absence of the disease can be affirmed from one symptom.

Case.—C. J., a Swedish servant girl, aged 30, was brought to the Policlinic Hospital, Monday, Oct. 26, 1894. The preceding Friday she had been taken with a severe pain in and above the left eye. The pain continued and she rapidly lost vision, first in the left eye, then in the right and when she entered the hospital she was totally blind. She was seen by the ophthalmologists, Drs. Coleburn, Mahoney and Wilder, who, finding no local trouble to account for the blindness, the following day referred her to me. I saw her, for a few minutes only, the same evening. Her pulse was 120, temperature 100 degrees F., tongue thickly coated: there was evidently marked prostration and considerable mental hebetude. When ques-

tioned she complained of extreme pain in the head, worse on the left side, especially in the frontal and temporal regions; the pain extended to the face, back of the neck and to a certain degree down the spine and there were some fugitive pains in the extremities. Marked tenderness to percussion was present all over the left side of the head and face except the inferior maxillary region, and to a lesser degree on the opposite side and along the upper spine. Cutaneous hyperesthesia was also marked, greatest where the pain was greatest but to some degree over the entire body. The head was not retracted but there was rigidity of all the extremities and the deep reflexes were abnormally brisk. The abdomen was not retracted but the patient was constipated and had vomited some. She was totally blind in both eyes. There was no perception of candle-light even as condensed by a two-inch lens, nor did the eyes follow the light or show, by other involuntary movement, recognition of the illumination. The fundi were normal, the pupils reacted promptly to light from all parts of the field and there were no ocular paralyses. Other cranial nerves were apparently normal except that she was totally deaf in the left ear. This deafness had come on since the beginning of the attack. As before stated, there was marked general weakness, but no localized paralysis and no anesthesia was discovered. There had been no convulsions. Thoracic and abdominal viscera were normal except a small patch of broncho-vesicular breathing below and internal to the angle of the right scapula. She was menstruating and the pelvic viscera were not examined. The foregoing data were too conflicting to allow of a positive diagnosis at once and I made none. I think it will be allowed that with a temperature of 100 degrees F., pulse 120, excruciating headache, pain and rigidity back of the neck, vomiting, constipation, foul tongue, hyperesthesia and increased reflexes it looked much like cerebro-spinal meningitis. But this would not account for the blindness without other ocular trouble, nor for the deafness without involvement of the facial. A meningitis with an abscess in the occipital region might have been invoked to explain the symptoms but the abscess would have to be large enough to destroy the visual centers in both hemispheres or cut the optic radiations of both sides posterior to the corpora quadrigemina. But there was no discoverable source of infection and the blindness had come on within forty-eight hours, too quickly for the development of such an abscess. An ice-coil was ordered to the head and the next morning found the patient rather more comfortable but in much the same condition as the previous evening. A more careful examination now showed that although she was deaf in the left ear and heard perfectly well with the right, yet when I spoke loudly into the left ear, the right remaining uncovered, she heard nothing. This was strong evidence, not of simulation, but of hysteria, and a prolonged search for stigmata finally revealed to the right of the sternum between the second and third ribs a spot of anesthesia about the size of a silver quarter. As I continued to examine and to try to accurately define this area it grew in extent until it reached the opposite side and up to the neck. I now felt reasonably sure of the diagnosis, or at least part of it, and as I had secured the attention of the patient by the examination of sensation, I immediately hypnotized her by simple suggestion. Fortunately, she was a good subject, although never hypnotized before, and in a few minutes suggestion had greatly ameliorated the pain and tenderness. The hypnosis with suggestion for the pain and tenderness was repeated in the evening with excellent results. The next morning she was quite comfortable and had a faint perception of light with the right eye. She was hypnotized and told that she could count fingers with this eye and on being awakened she was able to do so readily. A repetition of the treatment in the evening enabled her to read print. The left eye was still completely blind, but one sitting gave her perception of light, and the eye now followed the candle as it was moved about. The next morning she was given three sittings, one immediately after the other, enabling her in turn to count fingers, read print left eye, and hear perfectly with the left ear.

She remained in the hospital about six weeks but the further history may be summarized. No very severe symptoms appeared, but she was troubled by a number of minor ailments, some of them very annoying. Aching pains in the back, abdomen, chest and extremities, anorexia, emesis, constipation, insomnia and once retention of urine for a day and a half, at the end of which time it was drawn, were some of the symptoms. They all came and went and varied in intensity without apparent cause, and were generally tem-

porarily relieved by hypnotism, except the retention of urine and constipation. In connection with this case there are a few points that would seem, perhaps, to merit a more special mention.

Relation of the Headache to Loss of Sight.—Careful inquiry elicited the fact that the attack began as an ophthalmic migraine, that is, a severe headache with scintillating scotoma, or at least a play of lights and colors that she could not accurately describe; further, that about January, 1893, up to which time she had been perfectly well, she had a severe headache over and in the right eye, with impaired vision for a few days. About nine months before the present illness she had had a second and more severe attack on the left side, with complete blindness of the left eye lasting two or three weeks, and vision was still somewhat impaired when this last attack occurred, in which the pain distinctly preceded the visual trouble. Furthermore, during her stay in the hospital the most constant of her troubles was headache, and it invariably affected the visual function. When it was intense, as it was on one or two occasions, she would be unable to count fingers; if it were of moderate severity she would be unable to read ordinary print; when she had no headache her visual acuity was practically normal. The pain in the head was almost exclusively on the left side and it was as invariably the left eye which displayed the amblyopia. This difficulty in seeing could always be relieved by hypnotism, but what is of greater interest is the fact that suggestion directed against the pain *alone* would improve the sight. Again, when the pain was rather severe she had in addition to more or less amblyopia, marked dyschromatopsia, green and blue being lost, with greatly contracted fields for red and white. Relieving the headache by suggestion, not a word being said about vision or colors, never failed to remove the dyschromatopsia and enlarge the previously contracted fields. With the amblyopia she had at times diplopia or polyopia monocularis, which was also banished by relieving the pain. All of this goes to support the modern doctrine that hysteric manifestations are of purely psychic origin and due to the development of a sub-conscious imperative conception, the "idée fixe subconsciente" of the French. I do not like the term, but it seems better than any current one to express the process in these cases.

The Fever.—As before noted, the girl had a temperature of 100 degrees F. when first seen, and during almost her entire stay in the hospital it remained elevated. It was generally about 99 degrees F., never exceeded 100 degrees F., but seldom fell to the normal. At the same time the pulse was somewhat accelerated. The question of hysteric fever has been a bone of contention among pathologists and clinicians for more than a hundred years (Pomme, 1760-1782) and although its existence would now seem to be an established fact, yet in these days of recognized multifarious infection it must be repugnant to most of us to make, in any particular instance, this diagnosis. I have been loath to do so in my case and can only say that no other cause could be discovered. There seemed to be no probability of a malarial element in the case, but she was given an active course of quinin and arsenic. Although she was at times constipated, yet the bowels received attention³² and I

³² I saw some years ago in consultation a case of hysteria in which the attending physician had made a diagnosis of meningitis, and in which the fever was doubtless due to intestinal intoxication.

think intestinal infection may be excluded. She coughed at times, but râles were never heard and the cough had all the characteristics of a nervous affection. No sputum could be obtained for examination. The small area behind where respiration was slightly bronchial in character remained unchanged weeks after her fever had left. In short, no source of infection was discovered. Her temperature, moreover, was irregular, rose and fell without any apparent cause and eventually disappeared rather suddenly.

The *Relations of the Case to Hypnotism* may be very briefly stated. The patient went to sleep promptly at the first attempt; but it should be added that a friend had been treated by hypnotism in Stockholm so it was not entirely unknown to her. It was an efficient diagnostic and therapeutic aid although the diagnosis might have been made without it and other treatment might have been equally effective, if less rapid, in producing the desired results. Although hypnotic suggestion was so effective the patient was never unconscious and afterwards could remember all that had been said to her. For instance, she recalled perfectly being told that she could feel nothing with her left arm, but did not know that I had thrust a pin into it. I tried once one variety of what has been called hypnotism at a distance, although in this case as, I think, in all others, it was an instance of simple suggestion. As before noted, she suffered from insomnia and one morning I told her—not during hypnosis—that at nine o'clock in the evening she should think of me, imagine me with her in my usual place, count nine, and that when she reached nine she would fall asleep, as I would put her to sleep from my home. She did as directed and it succeeded admirably.³³ She subsequently tried this a number of times of her own accord without avail. I also tried post-hypnotic suggestion; this several weeks after she had left the hospital. During hypnosis I raised her arm and told her it was rigid and would remain so after she should awake until I should give her permission to lower it. When awakened the arm remained above her head. At this juncture I was called from the room and on my return after a few moments I found her just as I had left her. After some conversation, I asked her what her hand was doing up there and she replied with a rather shame-faced expression, "you know well enough I can't put it down."

The patient one day, several weeks after having left the hospital, asked me if I was the doctor who told her at the time she was blind to make a face at him (I had done so to test the facial) and I then learned that that was the only incident of my first examination that she remembered, there having been, as stated, considerable mental hebetude. I hypnotized her and then with some urging she recalled most of the details of the examination, and what is of greater interest, could remember them after coming out of the hypnosis.

These seemingly unimportant details are cited to show that the most profound hypnosis is not necessary for effective suggestion.

Venetian Building.

³³ Needless to say I did not think of her at all and that the process was one of auto-hypnosis.

PASTEUR's birthplace, the town of Dole in the Jura, has appropriated \$1,000 for a memorial to him, and solicits subscriptions from abroad to make it a worthier testimonial to this famous scientist.

AUTOSCOPY OF THE LARYNX AND OF THE TRACHEA.

Demonstrated before the Academy of Medicine in Cincinnati.

BY M. THORNER, A.M., M.D.

PROFESSOR OF CLINICAL LARYNGOLOGY AND OTOTOLOGY, CINCINNATI COLLEGE OF MEDICINE AND SURGERY; LARYNGOLOGIST AND AURIST, CINCINNATI HOSPITAL, ETC., CINCINNATI, OHIO.

Dr. Alfred Kirstein, of Berlin, has of late perfected a method of examining the air passages without the aid of laryngeal mirrors, which he calls *autoscopy*. This word indicates, according to the inventor, a method by which the interior portions of the larynx and trachea *themselves*, can directly be seen, and *not* their *image*, as we are wont to see it in the usual way of laryngoscopic examination. The writer has seen some of the early experiments with this method, and has been able to watch its development to the present state of perfection; and from these observations as well as from his own experiences with this method, he is prepared to say that the autoscope must be considered, to say the least, a very important addition to our armamentarium.

The development of this method from its beginnings is very interesting as it appears in the early publications of the inventor.¹ His first communication on this subject began with the words: "The usual method of laryngoscopy does not show us the larynx itself, but its reflected image. I have discovered, however, that the interior of the larynx is open to direct inspection in a great number of people; many manipulations in this region can be done under direct supervision of the eye, without the aid of mirrors, prisms or similar appliances." His instrument then consisted of a metallic tube, about 25 cm. long. It was introduced behind the well-cocainized epiglottis, while the patient was in the horizontal position with the head hanging over the edge of the table; and for better fixation, a Mikulicz-Rosenheim esophagoscope was previously introduced into the esophagus. It was possible by illuminating the laryngeal tube with electric light, to get a good view of the interior of the larynx.

But what a torture such an examination must have been to the patient! And what a difference between these first experiments and the present method of examination! I shall not detail all the different steps of evolution of the autoscope, but simply say that autoscopy as it stands now is the logical outcome of these early attempts.² The fundamental change from these to the present method consists in the substitution of the laryngeal tube by a spatula; and by the application of the fact that it is sufficient in some people to push the tongue downward and forward with an ordinary tongue depressor, to get a view of the epiglottis, the interior of the larynx, and sometimes even of the trachea. This fact is well known to everybody who works a great deal with the tongue depressor. It has been made use of by Reichert, when, in 1879, he described his method for

Centr. Ztg., 1895, No. 51. Autoskopie der Luftwege (Selbstschau, Besichtigung ohne Spiegel), Therapeut. Monatshefte, Juli, 1895. Autoskopie der Luftwege, Deutsch. med. Wochenschr., 1895, No. 38.

the elevation of the epiglottis in laryngoscopic operations,³ which mainly consists in firm pressure upon the root of the tongue and the median glosso-epiglottic ligament, whereby the epiglottis is readily elevated. Add to this the possibility of placing the body in such a position that the longitudinal axis of the laryngo-tracheal tube forms a straight (instead of an angular) line with the axis of the buccal cavity, and you have the two main conditions for the execution of this method.

The instrument, called by Kirstein the autoscope, consists of three parts, viz.: the spatula, the sliding hood and the handle.

FIGURE 1.

The spatula (Fig. 1, S.) is a slightly concave metal plate of 14 cm. length, which is in the main straight, but is slightly curved downward toward its laryngeal end (d). This extremity has also a somewhat thickened lip, and has well rounded edges to prevent injury to the parts with which it comes in contact. Here its width is about 1.5 cm., while the other, the proximal extremity, is about 2.5 cm. broad.⁴ At this end there descends at a right angle from it a square metallic bar by which it is connected with the handle by means of a set screw (a). The sliding hood (Fig.

FIGURE 2.

2) is 6 cm. long, and 3 cm. broad, is made in different heights, and is attached, by means of a sliding arrangement (Fig. 1, r), to the proximal extremity of the spatula. The hood serves the purpose of keeping the teeth, the lips and, in man, the mustache away from the spatula, leaving thus sufficient space between the two plates for inspection and for the introduction of any instrument. As handle most convenient the well-known electroscope of Casper is used, to which the spatula is attached at a right angle. This instrument contains a small electric lamp, the light of which is focused through a convex lens, and then deflected ninety degrees by the aid of a prism: thus the light is thrown along the spatula, in

the direction of the laryngeal cavity, which is brilliantly illuminated.

The technique of the examination is the following: The physician stands before the patient, who is seated on a chair (Fig. 3), with the neck slightly inclined forward. After connecting the electroscope with a battery, the circuit is closed by pressure upon the button, and the illuminated instrument is introduced into the mouth in exactly the same manner as in applying an ordinary tongue depressor. This is the first position, or pharyngoscopy, by which the usual picture of the buccal cavity and of the oral pharynx may be inspected.

In the second position (autoscopy of the lower portion of the pharynx), the spatula is gently pushed further backward, and the handle is gradually elevated, while a firmer pressure, directed downward and forward, is being made upon the base of the tongue. During this whole procedure the physician must by no means omit looking steadily along the well-illuminated instrument. It is now easy to overlook the entire anterior surface of the epiglottis with its ligaments and the valleculæ, a larger portion of the posterior and lateral walls of the pharynx, and sometimes also the arytenoid cartilages and the pyriform sinuses.

FIGURE 3.

This photograph was taken from a partly stripped patient in order to show distinctly the position of neck and head during examination.

For the third position (autoscopy of the larynx and the trachea), the handle is still more elevated, so that the plate of the sliding hood comes in contact with the upper incisors, whereby, however, every pressure on the teeth must be strictly avoided, and while the laryngeal end of the spatula now firmly depresses the base of the tongue in a downward and forward direction great care must be taken to not use the upper incisors or the alveolar process (in case a set of artificial teeth has been previously removed), as a fulcrum in order to exercise a firmer pressure upon the base of the tongue by leverage. During this procedure the slightly notched distal end of the spatula is receiving the median glosso-epiglottic ligament, upon which by means of the curved and thickened extremity of the spatula considerable pressure is exercised, whereby the epiglottis is elevated, so that the laryngeal cavity is now open for inspection. The arytenoid cartilages, the ventricular bands, the vocal cords, the interarytenoid fold, and the subglottic space are now readily seen. To examine the trachea the patient must stretch his neck a little more forward, without elevat-

³ Archiv für klin. Chirurg., Bd. 24, 1879.

⁴ The original instrument had a somewhat shorter, and decidedly broader, spatula, the laryngeal extremity was also not as much curved downward. The description and measurements given here are those of the best improvement.

ing or dropping the head (Fig. 3), so as to allow the axis of the laryngo-tracheal tube to come into a straight line with the axis of the buccal cavity. It is then possible to inspect the whole trachea down to the bifurcation, and the beginning of the bronchial tubes. The division of the examination into three positions is entirely arbitrary, and the various steps of an examination should never be done in an abrupt manner; on the contrary, it will ordinarily be carried out without any interruption, and with one or a few quick movements, and requires usually but a few seconds.

There may be a few obstacles to this method in some patients. Some people have such an irritable throat that they have to get use to these manipulations. In others again it is impossible to elevate the epiglottis sufficiently by pressure upon the base of the tongue. For such cases a special spatula has been constructed, the laryngeal end of which does not descend, but is level with the body of the spatula, and perfectly smooth. This spatula is introduced behind the epiglottis, which must have been previously well cocaineized, and in this manner the epiglottis is elevated. In all other cases one must be particularly careful not to introduce the spatula behind the epiglottis as this causes wrenching and coughing, and renders an examination impossible. In case of operative procedures the instruments (for instance curette, forceps, etc.) introduced into the larynx keep the epiglottis elevated. It goes without saying that instruments for autoscopic operations must be especially constructed for this purpose, *i. e.*, having a long (about 20 cm.), straight shaft attached to a handle at an obtuse angle, after the fashion of the nasal instruments.

This method has grown beyond the stage of a mere experiment; it is a fact. According to the inventor it is of equal importance for the specialist as laryngoscopy. It may be readily admitted that it is not an easy art; that it should be studied and practiced just as well as laryngoscopy and rhinoscopy. But the results are surprising to the observer who has been in the habit of examining the larynx exclusively with mirrors. It is true that there may be as yet a few shortcomings to this method; for instance, it is difficult to get a good view of the anterior commissure with the autoscope, at least in a number of patients; yet, as the inventor truly remarks, this is sometimes also the case with the ordinary laryngoscopic examination. However, the inventor himself, and those who have practised autoscopy and have some experience with it, do not insist upon saying that it will supplant laryngoscopy, or that it may be used in all cases. This would be exaggeration. But at this time it may be stated that it will prove a valuable adjunct to laryngoscopy to the physician, who knows when to use the one and when to apply the other. I may state from a somewhat extended personal experience with this method, that it is, in skilled hands, by no means painful to those patients, in whom it can at all be exhibited; and their number is by no means so small as it might appear to those who first attempt to use the autoscope. And you may notice that this patient whom I used for this demonstration, does not show the least uneasiness. It requires only some patient practice with this instrument, in order to become familiar with the proper manipulations, which must be firm and decided, and yet gentle, and to a certain extent, yielding. If thus

executed, autoscopy will in most cases be considered only moderately disagreeable by the patient. And in spite of its disadvantages it certainly has some great advantages. The actual tissues appear in autoscopy before the eye of the physician, and not their image, and the anatomic details appear with a clearness that must be seen to be appreciated. Above all, the posterior wall of the larynx, the interarytenoid fold, which can be examined only with great difficulty by the aid of the mirror, can be inspected almost in a surface view; and the possibility of inspecting the whole of the trachea, and the beginning of the bronchi would alone be sufficient to insure for autoscopy recognition among our most valuable diagnostic and therapeutic resources.

PULMONARY TUBERCULOSIS—ITS DIMINISHING PREVALENCE.

BY EDWARD F. WELLS, M.D.,

CHICAGO.

In a paper presented, several months ago, to the Chicago Medical Society, I enunciated the proposition that pulmonary tuberculosis is declining in prevalence, and supported the assertion by some condensed statistical tables. The conclusions arrived at, although neither novel nor surprising, have met with no hearty acceptance. On the contrary, I have been informed that my deductions were extracted from an array of facts much too circumscribed; that a careful survey of a wider field would show other and differing premises; that my conclusions were misleading; that the prevalence of pulmonary tuberculosis has, in fact, undergone no decline. Recently I have tabulated statistics from a broader field, as suggested, with the result of confirming the opinion previously expressed.

Readily accessible medical literature gives us very little information upon this subject.

Weitemeyer¹ informs us that in Munich during the 75 years from 1814 to 1888, there were 329,862 deaths from all causes, and 47,282 from pulmonary tuberculosis, equal to 14.33 per cent. In periods of 25 years the proportion was as follows:

First 25 years	15.34 per cent.
Second 25 years	14.93 " "
Third 25 years	13.71 " "

The decline is equivalent to 10 per cent.

In the same city the death rate from pulmonary tuberculosis, per 1,000 of population, was, in 1883, 4.08, and in 1893, 3.08, a decline of 24.5 per cent.²

Hollinger³ gives the following additional statistics:

Berlin, 1883	3.47 per 1,000 of population.
" 1893	2.57 " "

A decline of 54.8 per cent.

Vienna, 1883	6.92 per 1,000 of population.
" 1893	4.70 " "

A decline of 31.7 per cent.

Simpson⁴ states that in the 11 years, 1873 to 1883, pulmonary tuberculosis declined in prevalence in the North of Scotland.

Borden⁵ gives an example of extraordinary susceptibility and increasing fatality in the case of the Apache Indians, as follows:

Average annual population	388
Deaths from pulmonary tuberculosis	15.6
Rate per 1,000 of population	40

Being averse to burdening medical literature with any unnecessary matter, especially of a statistical nature, I addressed a letter to each of twelve of the foremost physicians of this country requesting an answer to the following question:

"Is pulmonary tuberculosis increasing or decreasing in prevalence, and, if either, to what do you attribute the change?"

Of those who kindly replied to the interrogatory not one gave an answer satisfactory to himself. Each stated that the opinion which he expressed was based upon personal impressions and experience and not upon statistical evidence. In the majority of instances the fact is mentioned that the writers were unable to refer to any statistics upon this subject. It would seem, therefore, that the material presented in the accompanying tables will not be found useless or superfluous.

As already stated, the tables show a marked, widespread and steady decline in the prevalence of the malady under consideration. This is so clearly and graphically shown as to render any extended comment in the text unnecessary.

TABLE I.—MORTALITY OF PULMONARY TUBERCULOSIS PER 1,000 OF POPULATION.

TABLE III.—MORTALITY OF PULMONARY TUBERCULOSIS PER 1,000 OF POPULATION IN THE UNITED STATES.⁶ Decennial Census.

Years.	Population.	Deaths from Pulmon. Tuber.	Per 1,000 of Pop.	Remarks.
1850	23,191,000	33,516	1.45	Average for five decennial years, 1.65. Increase of 12 per cent.
1860	31,443,000	49,082	1.56	
1870	38,558,000	68,896	1.79	
1880	50,156,000	91,551	1.82	
1890	62,622,000	102,199	1.63	

Although in the case of Ontario, Savannah and the United States there is shown to be an increase in the prevalence of pulmonary tuberculosis, I believe that an intelligent and comprehensive review of the statistics presented in the tables will confirm the opinion which I have expressed, viz., that the malady has decreased in prevalence during the recent past, and that the tendency is toward a further reduction.

34 Washington Street.

TWO CASES OF EXTENSIVE EXCISION OF THE ELBOW JOINT, WITH REMARKS.

Read by title in the Section on Surgery and Anatomy, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY GEORGE FRANKLIN SHIELDS, M.D., C.M.,
F.R.C.S.E., L.R.C.P.
SAN FRANCISCO, CAL.

In the following report of cases and observations thereon, no description of the various operations for excision of the elbow joint will be introduced, since the writer is of the opinion that the time of the Surgical Section is too valuable to be used in placing before its members a résumé of that which may be found in any work on general or operative surgery. It will be sufficient to say that in both cases the single posterior median incision was used, and that the customary care was taken in clearing the bones and sawing them through.

Case I.—Miss F., aged 24, of Jacksonville, Ill., was April 27, 1892, thrown from a buggy, sustaining a severe comminuted fracture of the condyles of the right humerus, which extended to the elbow joint, as well as a fracture of the olecranon process of the ulna. The doctor who first saw the case put up the arm in a straight position, using a posterior splint which was replaced in two weeks by a plaster cast, this being removed during the third week, when the patient was told to exercise the arm. This she was unable to do, as she could neither flex the arm nor pronate or supinate the forearm. After visiting several surgeons, who informed her that nothing could be done, she started for the Sandwich Islands as a school teacher, and

⁵ Boston Med. and Surg. Jour., July 6, 1893, p. 8.

⁶ The writer desires to return thanks to the registrars of the various cities referred to for valuable and special statistical information, and to the gentlemen who so courteously sent replies to his letter of inquiry.

en route called upon me while in San Francisco in October, 1892.

When I saw her the condition was as follows: The general health of the patient was bad and she might be described as being generally "run down." The elbow was ankylosed so that the forearm was at an angle of 135° to the arm. She could neither supinate nor pronate the forearm, which occupied a position slightly nearer supination than pronation. All the muscles acting on the elbow joint were atrophied, and the arm was from its position practically useless. The elbow joint was obliterated by a callous mass which gave it a swollen appearance, and this was painful on pressure and on attempts at forcible motion.

On consultation with Dr. J. F. Morse, surgeon to the German Hospital in San Francisco, it was decided that nothing short of excision of the destroyed joint could be of any benefit. The patient agreed and the operation was performed. As soon as the incision was made and efforts at clearing the bones were begun, we found that inflammation of the lower end of the humerus had occurred and that the bone was so disorganized that it would be necessary to remove an unusually extensive portion to escape diseased tissue, so with great misgiving we sawed the humerus through an inch above the margin of the olecranon process. The arm was put up at right angles. At the end of the first week passive motion was instituted, and in the course of the second week the forearm had been gradually carried through various angles until it was brought from full flexion to full extension. This passive motion was continued throughout the whole course of the treatment. On the third week the wound was healed with the exception of a small sinus which led down to the lower end of the humerus, and as this would not heal it was laid open, when we were enabled to remove a ring of bone which had necrosed and which was about one quarter of an inch in length. The wound now readily healed, and the patient commenced voluntary efforts at flexion and extension, but the limb was like a flail and would fall from one side to the other in a helpless manner. In order to correct this I had made a steel joint to take the place of the internal and external bony and ligamentous lateral supports, and to my gratification the patient rapidly improved her power of motion and moreover developed an extensive pronation and supination, which she aided by rotation of the humerus.

When I last heard of her she was able to play the piano, dress and feed herself, "do up her back hair," and when dressed could readily conceal her injury except to the practiced eye, which would of course notice the shortening.¹

Case 2. R. O., aged 26, was struck by a piece of iron on the tip of the left elbow on March 1891. The joint was swollen and painful and the arm fixed in the extended position remaining so for a year, when efforts were made to forcibly flex the joint. This led to increased pain and stiffness and subsequently an abscess formed just above the olecranon process, which opened itself and continued to discharge up to the time when I first saw him in March 1893. On examination a sinus was found to lead down to a caries of the olecranon and also of the articular surface of the humerus. The joint was swollen and all the bones going to form it were thickened. The arm was fully extended and there was no power of flexion, extension, pronation or supination. The muscles of the arm and forearm were much atrophied.

Excision of the joint was advised and agreed upon. The operation showed the joint to be tuberculous and it was necessary to remove half an inch of the shaft of the ulna as well as an unusually large portion of the humerus, the section being made about half an inch above the margin of the olecranon fossa. Only the upper portion of the excision wound was stitched and the cavity (after extensive curetting and free use of the scissors to remove suspicious tissue) was stuffed with iodoform gauze.

The after-treatment was much the same as in case 1, except that no steel joint was found necessary. At first there was a tendency to a flail joint but the parts contracted and the muscles adapted themselves to the new conditions.

The eventual result will be best understood by using the patient's words when I saw him yesterday to remove a small piece of bare bone two years after the original operation.

I asked him what he had been doing; he said that he had been washing dishes, picking fruit, waiting on table and wood-chopping, all of which occupations require that the elbow joint should have extensive motion. I then requested him to go through the motions of extension, flexion, supination and pronation with his coat on in the presence of two doctors who, when asked what was the matter with him (not knowing of the operation) said that his arm was congenitally shortened.

In commenting on these two cases let it be said that there is nothing unusual except the extensive removal of bone and it is to this that I desire to call particular attention, in fact it is the sole reason for the present report. In case 1, both my consultant and myself on discovering the extensive destruction of the humerus felt hopeless as to the future possibility of obtaining a movable joint, and it is indeed strange that the muscles could so adapt themselves to the new conditions that an almost normal range of motion resulted, even with the aid of a mechanical steel hinge. I desire to call attention to the fact that the collar which surrounds the forearm need only be tight enough to keep the apparatus in position and does not interfere with supination and pronation of the forearm. In case 2 it seemed almost foolish to attempt anything but amputation, but with the memory of case 1, as a guide, the operation was not only done but proved most successful and instead of an armless cripple we have a man who when dressed and ordered to go through a wide range of motion makes it difficult for even a medical man to diagnose his condition.

I trust that these two cases may in some slight measure demonstrate the fact that even extensive removal of the elbow joint may be followed by good results, and that one should hesitate in cases of extensive destruction before he is satisfied with either a stiff joint or decides to amputate the limb, since he can always carry out either plan should efforts for a movable joint fail.

32 O'Farrell Street, San Francisco, Cal.

BACTERIOLOGY.

Read in the Section on Dental and Oral Surgery, at the Forty-sixth Annual Meeting of the American Medical Association, at Baltimore, Md., May 7-10, 1895.

BY S. A. HOPKINS, M.D.

BOSTON.

I am sorry to be obliged to preface my remarks with an apology, but when I accepted the honor of addressing this society, I had in mind certain original work upon which I was then engaged and which I hoped to have completed in time to lay before you in this paper. I regret to say that in this I am disappointed. As you well know, the demands of science are hard to fulfill. She has little respect for the limitations of time and strength of her votaries. While, therefore, I shall be able to offer you but little in the way of original work, I am very glad to have this opportunity of speaking to you on a subject that is of the deepest interest and significance to me, and which I trust may in its future development prove to be of the greatest practical value to us all.

We have as specialists in medicine in the department of oral surgery made such remarkable advances in recent years in the practical operations for the relief of pain and to restore the teeth to the highest

¹ Jan. 17, 1895. Since the above report I have received a letter from the Sandwich Islands in which Miss F. informs me that her arm has grown stronger steadily, and that she can now "put up an eight pound dumb bell above her head."

degree of usefulness that we are puzzled to know how to go further. The degree of skill that a dentist may exercise in his calling can not be easily overestimated. It is not going too far to say that in the performance of the most difficult surgical operations no more delicate touch, no higher degree of skill can be exercised than is called forth in your daily practice. A high plane has certainly been reached in the direction of practical operations, but I feel sure that there is another direction in which our mental activity has not yet had full scope, and I am convinced that in the study of pathology and especially in the study of bacteriology there is a rich field to be cultivated and a splendid harvest of scientific truths to be garnered. By a brief outline of the general subject of bacteriology and by a hasty reference to the specific work which bacteria perform in both health and disease, I shall endeavor to point out to you the importance of this science in general medicine, and I shall briefly call your attention to its possibilities as applied to oral diseases and the destructive processes that go on in the human teeth.

It is a subject for comment that when in the latter part of the 17th century Lieuwenhoek made his wonderful improvements in microscopes and thus prepared the way for and made the study of bacteriology possible, some of his first researches, his first discoveries, were made in connection with the microorganisms of the human mouth. The study of bacteriology may be said to have begun with the improvements in microscopes that I have just mentioned. It was Koch's discovery of the solid culture media that placed the work on a scientific basis and made possible investigations that up to that time could not have been made. It was Pasteur's application of the new science in the treatment of anthrax and other diseases that made bacteriology practical as applied to the treatment of diseases and opened to the world a new method of treatment which bids fair to outshine in its usefulness and scientific accuracy all previous knowledge of curative medicine. The limitations of this paper will not admit of even the mention of the names of many other eminent scientists who did important pioneer work in this field, but no mention of this science, however, brief, can be made without reference to Lister's work, with which we are all familiar. The thousands of lives saved by antiseptic surgery will be an everlasting monument to his name. Much of the pioneer work in the study of mouth bacteria has been done by Möller of Berlin, who has made important discoveries and written an excellent work on the subject that will repay careful study. In our own country, the Surgeon General of the U. S. Army, George M. Sternberg, has written the most comprehensive and exhaustive manual of bacteriology that has yet been published. When we consider the immense amount of original work which this volume contains, and consider how large a part of it was done while hampered by the limitations of an army life, we can not but wonder at the courage and persistence of the man, while we accept the reflected honor of naming him as our countryman. I wish to give credit to G. Sims Woodhead of Edinburgh, to Prof. Sedgwick of the Massachusetts Institute of Technology, and to Prof. Ernst of the Harvard Medical School, for many suggestions offered in this paper.

Bacteria were originally supposed to belong to the animal kingdom, but it is now known that they are

vegetable microorganisms. It is important to get this firmly fixed in one's mind, for while it is known that microorganisms belonging to the animal kingdom exist, and play an important part in the economy of life, yet it is an erroneous and most unfortunate misapprehension of facts which places bacteria in the same class. I am convinced that a great deal of the repulsive feeling which is aroused in every layman's mind by the mention of bacteria is largely due to this misconception. I am sorry to say that this error is not wholly confined to laymen, for it has been my misfortune to frequently see trained physicians express surprise when it was asserted that bacteria were vegetable microorganisms. I do not think the importance of bacteriology has yet been understood or appreciated by the public, who have been slow in giving their support to this science, and popular support we must have if we are to give mankind the benefit of our labors in any field; hence any misconception of facts which is likely to prejudice the mind of the public against a science is to be regretted. The bug theory, therefore, should be laid aside, and this important factor in our lives relegated once and for all to the domains of botany where it belongs. (Charts showing some of the common forms of bacteria, cocci, bacilli, spirilla, parasites, saprophytes, aerobic, anaerobic, motile, non-motile).

It is a curiously fixed belief in the popular mind that bacteria necessarily means disease. Of course we know nothing could be more unfortunate than this belief, for it serves only to create a panic in the minds of people less familiar with the subject which can not be easily quelled. It is true that many of our most fatal epidemics have been traced to these infinitesimal organisms. They and they alone have been proved to be the essential factor in the production of many diseases. Undoubtedly there will be many more convicted of guilt, but we should not lose sight of the fact that the great army of bacteria, so far as we know, are harmless, while many forms render most beneficent and important services to mankind.

The world of bacteria seems to my mind to bear a close analogy to the higher vegetable world with which we are more familiar. We have among bacteria almost as great variety of shapes and forms as among the higher orders of plants, and the shapes and sizes vary in different soils or culture media. Certain forms grow best in some particular soil or culture medium and will die if not cultivated in a suitable medium, just as the higher plants develop best in soil and under conditions best suited to their growth. Some forms, like our common weeds, seem to have no special object in nature, or at least their usefulness has not yet been ascertained, and certain varieties of plants will be crowded out and die if others are allowed to grow in their vicinity. Certain bacteria produce spores almost analogous to seeds, which retain their vitality long after the death of the plant, and spring up to life again when planted in suitable soil under suitable conditions. Some bacteria, like the noxious weeds and poisonous plants, create havoc in the human race, but the wisdom of creative intelligence has not failed in the creation of bacteria any more than in the higher vegetable world, and has made life itself dependent upon their intervention. These infinitesimal organisms are as necessary to existence as are the higher plants, and the latter would cease to flourish were it not for the

presence of bacteria. Without the aid of these microscopic bodies some of the most essential and at the same time the most familiar and common-place processes of nature could not be carried on. Our farming operations are dependent upon them, and the farmer, without being versed in the higher sciences is putting forth in the cultivation of his crops his best efforts to encourage the action of the bacteria in the soil, without which he could not raise a crop. These infinitesimal allies of the farmer convert the excrement of animals and plants into simple constituents necessary for the development of plant life. (Prof. Sedgwick's plate).

Beginning with the nitrates, plant life is evolved with the aid of the sun's rays, until it is converted into living vegetable matter, which in turn may be converted into animal. From this position at the top of the chemic scale we find it first decomposing into nitrogen and organic nitrogen, that is, albuminoid ammonia. The next step is nitrogen as free ammonia. The next step is its conversion into nitrites, and the last step is from nitrites to nitrates, where it began its existence as plant life. These changes are brought about by the action of the nitrifying bacteria. The expression sterile land is strictly scientific, for no sterilized land, land that is free from bacteria, can afford support to the human race. It would be interesting, if time permitted, to show in detail the work of these bacteria. We find that in cultivated lands they predominate in great numbers, in fact the object of cultivation is to break up the land in such a way that the conditions that are best suited to the development of a great many bacteria shall be fulfilled. In land that has not been disturbed for a long time we find very few bacteria at a greater depth than one meter below the surface, but in cultivated land we find them in abundance at a much greater depth. The effectiveness of bacteria lies largely in the fact of their being reproduced in such enormous numbers in an almost infinitesimal space of time. It is estimated that a gram of earth in the superficial layers may contain anywhere from 5,000,000 to 50,000,000. In the dirty and crowded thoroughfares of Naples the number of bacteria to one gram of dust is not less than one billion. If any argument were needed to illustrate the dangers of mouth breathing, it might be found in the statement I have just made. Fraenkel and Wynogradski have both described a form which has this nitrifying power of which I have spoken, but it is probable that this process does not depend upon any one form, but is brought about by the labors of many different varieties; but these forms, like many of the mouth bacteria, do not grow readily on the usual culture media, and their study is attended with great difficulty.

In connection with the bacteria which are found in the soil, it would not be out of place to say a few words in regard to the work which they perform in connection with sand filtration. Purification of the water in the pockets of the earth is brought about by sand filtration. It has been known for many years that under certain conditions sand forms a perfect filter, but it is only within recent years that we have known the method of this operation. This has been taught us by the study of the bacteria of the soil. We have seen how the organic matter which finds its way on the field in various forms of decomposed vegetable and animal matter is taken up and converted into plant life, and we find that much the same pro-

cess goes on in sand filtration. If you constructed a filter of clean sterilized sand and then poured contaminated water or sewage into it, you might find that the water as it came through was quite clear to look upon, but on a chemic and bacteriologic examination being made, you would find it teeming with organic matter, and possibly pathogenic bacteria, and entirely unfit for use. But if you continued to pour the filthy water through and examined it as before, you would notice that as the filter grew older the water became purer, and after a certain time, provided there had been free access of air, and you had not poured the filthy water through so fast as to mechanically clog the filter, you would find that perfectly clear water percolated through, and upon subjecting it to chemic and microscopic tests you would find that it was pure. You would also find that it would continue to be pure as long as the filter was not overcrowded and had a plentiful supply of oxygen. Now what has happened? Microorganisms capable of destroying organic matter have attached themselves to the particles of sand in the filter and are performing the same office here as in the soil, and they will continue to do so as long as the filter is properly used. Thus we have science of bacteriology simplifying the question of the water supply of the world.

Many of our large cities are already approaching the end of their possibilities as regards the natural supply of pure water, and in the great majority of our large cities and towns it is a serious question as to when the water supply will be exhausted. The time is apparently not far off when we shall be able to construct filter beds and establish bacteriologic laboratories in connection with the water works of every large city and town, and when the fact is firmly established that filter beds actually filter, and the public mind has been set at rest on this subject, we shall be able to take our water from the nearest river, and be surer of having it purer than that for which we now pay millions of dollars to procure from some distant mountain rill or crystal lake. This work has been going on with great success in the city of London for years. London at the present time employs over a hundred and twenty acres as filter fields, and the difference in typhoid fever rates between London and outlying districts which are not supplied with London water is very marked indeed.

There is an interesting case of a town, Altona, which might be called a suburb of Hamburg, lying as it does some few miles out of the city, and which takes its water from the Elbe at almost the same spot from which Hamburg is supplied. During the cholera epidemic at Hamburg a few years ago there were no cases of cholera in this town until an accident happened to one of the filter fields. From this cause a few cases of cholera were developed, but as long as the people had used water filtered in this way, although they were drinking precisely the same water as the city of Hamburg, no harm came to them. The city of Lawrence, Mass., has recently subjected its water to sand filtration with remarkable results in the reduction of typhoid and similar diseases, and many other towns are following the example of Lawrence. Of course the remarkable rapidity with which bacteria act is dependent upon their vast numbers and the rapidity with which they multiply. The number of cocci in one millegram of a pure culture has been estimated at eight billion. If further evidence were needed to show the important part these infinitesimal organ-

isms play in our daily life, the familiar ferments of bread, cider, vinegar, wine and beer need only to be mentioned. It is probable that many of the physiologic processes that go on in the body are greatly dependent upon these microorganisms. Indeed, it has come to be a question whether life itself could be carried on without the intervention of bacteria.

I have thus briefly mentioned the work done by non-pathogenic bacteria in order to emphasize the great field the science of bacteriology has before it as applied to the arts and sciences. We as physicians, whether we are in general practice or particularly concerned in the specialty of dentistry, are more interested in the pathogenic forms. I have selected a few of the diseases with which we are more or less familiar, and which have an acknowledged bacteriologic origin, in order to point out some of the work that has already been accomplished in this direction. It must be remembered that pathogenic bacteria are for the most part parasites feeding upon living matter, and the difficulty in cultivating them is greatly increased by this fact, because it is impossible to employ living culture media. Therefore the more strictly pathogenic the form is, the more difficult it is to cultivate. Until we advance a great deal farther in the making of culture media we can not hope to isolate and study the bacteria of many diseases which are acknowledged, if analogy goes for anything, to be of bacteriologic origin. As an example of pathogenic bacteria and the spread of disease, the cholera bacillus has an especial interest.

Asiatic cholera was for ages looked upon as a devastating plague. Its origin and method of development were for many years hidden mysteries, and mankind was helpless and almost hopeless in coping with this awful destroyer. To-day, while there are sporadic cases which it is difficult to trace and hard to explain, the evidence accumulated by Koch and others leaves no question but that cholera is a parasitic disease, and that the comma bacillus is the active agent in its production. This theory of the comma bacillus is not, however, accepted by all scientists, and the investigations of such a careful worker as Pettenkofer are not to be lightly passed over. He and his followers maintain that cholera is caused by the lowering of the ground water in the pockets of the earth, and it can not be denied that the spread of the disease bears a causal relation to this phenomenon. But it is also true that meteorologic and other conditions which cause the lowering of the ground water and the increase of the drying zone are the very ones best suited to the development of the comma bacillus, and it requires no stretch of the imagination to reconcile the two theories.

Pettenkofer's theory of the ground water and drying zone serves, when rightly considered, only to support the theory of Koch, which is the only theory which will stand Koch's tests. The laws of Koch, in the tests which are to be applied to all pathogenic forms of bacteria, are three. 1. The organism must be of constant occurrence in the disease. 2. The organism must be cultivated and pure cultures obtained. 3. It must be able to produce a pathologic process exactly the same or similar to that which is produced in the normal course of the disease when inoculated into susceptible animals. In the case of the cholera bacillus the last condition or the third law was fulfilled not without difficulty, from the fact that the acid juices of the stomach had a marked

effect in destroying the bacteria, but by certain processes which I have not time to describe, Koch and others were able to cause the same pathologic conditions in lower animals by inoculation of cultures of the comma bacillus that takes place in the patient suffering from Asiatic cholera.

Cholera is endemic in the delta of the Ganges river. In Persia, Asia Minor, and in China at the mouth of the Yangtse it breaks out with regularity year after year. It is brought into Europe by the ships of commerce and other vehicles of travel, and several of the worst outbreaks have been caused by the return of the Mecca pilgrims. Overcrowding and lack of hygienic measures bring about water contamination, and meteorologic conditions favoring the development of the bacillus contribute to the spread of the disease. The specific organism is, roughly speaking, shaped like a comma. It varies in length from 1 to 2 μ and is about .5 μ in thickness; it sometimes occurs singly, sometimes in groups, and frequently has the appearance of irregular curves. Many bacteriologists consider this organism a spirillum form of which we see only broken portions. Like many other forms of bacteria the organisms present slightly different appearances when grown on different media, and there are slight differences in culture from different localities. It is said that an expert can take up certain cultures and say, this is from Shanghai, this from Egypt, this from Naples, and so on; but the microscope reveals the same characteristic comma-shaped forms in all. They grow on almost any material that is not acid. Acids destroy, and the presence of other bacteria in the culture also destroys the cholera bacillus. This fact suggests a possible means of treatment, and work is being done to ascertain the possibility of treating cholera patients by the introduction of other harmless forms. The fact that the comma bacillus is so readily destroyed by acids gives rise to the query, why are they not destroyed by the gastric juice of the stomach? Pettenkofer, Klein, Boichfontain, a New York *Herald* reporter, and doubtless thousands of others, whether intentionally or not, have swallowed the bacillus in milk, water, vegetables and other food without injury, and their immunity doubtless depends largely on the power of the healthy gastric juice to destroy this organism. It is proven beyond doubt that derangement of the stomach and intestines is one of the conditions which are favorable to the development of the disease; and that a reduction of the acid of the gastric fluid by such a disturbance may encourage the development of the organism is altogether probable.

Sailors who go ashore in an infected port, especially when they spend the night drinking and rioting, and have the usual morning derangement of the stomach in consequence, are particularly prone to the disease; and to the Mecca pilgrims, to whom I have referred as being responsible for some of the epidemics that have broken out in Europe, offer favorable conditions for its development from the wasted and unwholesome condition that is brought about by travel and fasting. These conditions lead to gastric and intestinal disturbances which are favorable to the development of the bacillus. Steerage passengers upon crowded vessels are apt to present conditions favorable to an outbreak. The gastric juice of the healthy stomach will in all probability kill these microorganisms. That fact does

not permit of our relaxing our vigor in sterilizing food and water during a cholera epidemic. We can never be quite sure that the gastric juice is in good condition, and the sterilization of everything that goes into the mouth in the nature of food and drink would crush out the most fatal epidemic immediately. Cleanliness and proper attention to hygienic measures will do much to prevent the spread of the disease, and it will be a government crime if it even obtains a foothold in this country; but it is human to be careless and to take chances, and even though we know the exact way the disease is produced and developed, it will not in all probability seriously mitigate against future outbreaks until knowledge of bacteriology becomes more general than it is to-day.

Of typhoid fever, time will not permit me to speak, except to say that the bacillus has been isolated, and while attempts to produce it on animals have not met with success, most animals being immune to the disease, and we can not very well inoculate human beings, yet the microorganism has answered all the other tests, and the evidence is undoubted that it is the cause of typhoid fever. The water supply, in this case contaminated by the dejecta of typhoid patients, is again the most common agent for the spread of the disease. Milk diluted by water from a contaminated source, or milk cans washed in contaminated water, has been the cause of more than one epidemic. Recently at a Wesleyan College in Connecticut an outbreak was traced to some oysters the students had eaten. It was found upon investigation that these had been taken from their original bed and deposited at the mouth of a fresh water stream to freshen and fatten, and investigation showed that the stream was contaminated by the feces of persons suffering from typhoid, and the source of the epidemic was proven beyond a doubt. Although contaminated water supply can not be responsible for all cases, it certainly is for the principal epidemics of typhoid fever, and most outbreaks can be traced to the pollution of the stream by the feces of patients suffering from the disease.

We pass to a brief consideration of tuberculosis. Tuberculosis is of interest not only because it is an exceedingly common and widespread disease, but because an immense amount of bacteriologic work has been done in its study and in the attempt to find a satisfactory method of treatment. I may add that it is also interesting from the fact that bacteriology was dealt a serious blow in connection with this disease by the ill-advised use of Koch's lymph, or as it is now known, tuberculin. If time permitted, I should like to detail the steps of Koch's studies and to outline the results which he hoped to attain, and did attain in a measure. I am one of the few who still believe that in tuberculin or in some modified form of tuberculin, we shall have a valuable addition to our methods of treatment in this disease. Koch's labors were incomplete when he was forced to make them public. They were not satisfactory, and the entire ground will have to be worked over again very carefully. When this is done I have no doubt that Koch will be acquitted of having committed what at this time seems a serious error. Koch's tuberculin as a means of diagnosis for diseased cattle seems to have answered all the required tests, and inestimable benefits will undoubtedly result from the destruction of tuberculous animals. We are just now going through a period of somewhat heated discussion as to the

value of tuberculin as a means of diagnosis, and I prefer not to express too positive an opinion. Whether the danger from tuberculous cattle is as great as has been assumed, I am not able to state, but the fact that healthy animals are to be preferred to those suffering from tuberculosis is plainly evident, and if we can be aided by tuberculin in determining this fact, it will certainly prove a great blessing.

The bacillus of tuberculosis is a delicate rod about 2.5μ in length and from $.2$ to $.5 \mu$ in width. It does not stain as readily as many others, and care must be taken in preparing the cover-glasses for the microscope. It is difficult to cultivate on artificial media; it is also difficult to obtain in pure cultures. It is, however, constantly present in all tuberculous lesions, whether they appear in the lungs, in the intestines, liver, membranes of the brain, eruptions of the skin, or any other region of the body. It does not follow that all degeneration of lung tissue is caused by tuberculosis. It is extremely probable that other forms of pathogenic and pyogenic bacteria may be found to be responsible for many destructive changes in the lung tissue. The disease, although it carries off a larger proportion of our people than any other disease, still must not be considered hopeless. We are beginning to realize more and more each year, that much can be done to prevent the spread of consumption and much to prolong the life and improve the condition of the sufferer from this disease. The importance of an early diagnosis is apparent, and this can best be accomplished by a bacteriologic examination of the sputum of suspected cases. Examinations must be made at frequent intervals, as it is not improbable that a great many negative results may be obtained before the bacillus is discovered. If once discovered, however, even if the number is very small, treatment should not be delayed. Begun in these early stages, the prognosis is by no means hopeless, and a diagnosis can frequently be made in the way I have indicated long before it is possible to determine the condition by physical examinations and percussions. Important as the diagnosis and treatment of the disease must seem, the prophylactic treatment is vastly more important. The dry sputum of the tuberculous patient is the principal cause of the spread of the disease, and we well know to our sorrow how a disease spreads through a family, to such an extent that up to within recent years it was thought to be an inheritance for which there was no responsibility and from which there was no escape. While it is true that the conditions which make the reception and development of the disease easy may be inherited, the disease itself is not. When we realize how the dried sputum in handkerchiefs, spittoons or anything else upon which it may have been deposited can be wafted through a room by the slightest disturbance of the air and find a suitable field for development in the lungs of some other member of the family, we do not need the theory of inheritance to explain its spread. So tenacious of life under certain conditions is this bacillus and so easily distributed by currents of air, that were I about to hire a house, particularly a furnished one in which consumptive people were known to have recently lived, I should feel like taking the same precautions regarding sterilization and disinfection that would be necessary after diphtheria or smallpox.

The responsibility of dentists as well as the danger

they encounter from exposure to this disease is worth considering. For his own protection as well as that of his patients the dentist should see to it that his napkins, spittoons, and instruments are carefully sterilized. This process can not be too thorough, because the danger is a real one, and exposure may come at any time. Considering the number of mouth bacteria that our napkins, instruments, etc., come in contact with each day, considering that most of the pathogenic varieties of bacteria enter the system through the mouth, it seems as if sterilizing methods should be employed in the most careful manner by every dentist. We can not work under strictly antiseptic conditions, it is true, as it would be impossible to sterilize the juices of the mouth or the atmosphere of the operating room. While we can do much to render the possibility of infection from these sources as remote as possible, we are only responsible for the transmission of disease from one patient to another, and the dentist who neglects to sterilize his instruments after using, has a fearful responsibility on his conscience.

The bacillus of diphtheria is of interest to oral surgeons not only because it is found in the mouth and throat, but because of the almost sensational interest that has been aroused by the treatment of this disease by inoculation of antitoxin. The bacillus, which is known as the Klebs-Löffler, is a rod of varying length, with rounded ends, somewhat resembling a club in shape. The bacilli are slightly curved, and have a tendency to arrange themselves in pairs. It is not, however, by any means an easy matter to distinguish these microorganisms from others under the microscope. I have myself seen forms which it was impossible to distinguish by the microscope alone from true diphtheria. One of these forms that I have mentioned came from a cavity in a molar tooth. This emphasizes the importance of making cultures on different media, and not trusting alone to the microscope in bacteriologic examinations.

As a matter of fact, bacteria are almost sub-microscopic; they are too small to be studied by the microscope alone, and any conclusions that may be arrived at from this method of study should be confirmed by making cultures and noting the growth of the organism.

(To be continued.)

THE CLINICAL VALUE OF THE FREE DISPENSARY.

Read at the Meeting of The Doctors' Club, Oct. 25, 1895.

BY THOMAS A. DAVIS, M.D.

President of the West Side Free Dispensary; Associate Professor of Surgery, College of Physicians and Surgeons; Surgeon to and President of the Medical Staff of Cook County Hospital, etc.
CHICAGO.

Mr. Chairman and Gentlemen:—I did not know until yesterday afternoon (through the *Chicago Tribune*) that papers were to be presented here to-night; but understood there would be some little effort at extempore discussion in defamation and laudation of the dispensary system. I was glad to see the preparation for so thorough consideration of the subject from such practical standpoints and by such distinguished gentlemen, and I am sure that, though I can offer but little of interest myself, I shall have learned much, and by the application of such knowledge do sufficient good to compensate for my shortcoming in relation to the present meeting.

The dispensary is an old institution, originating in the seventeenth century from philanthropic people as a protection to the sick poor against the greed of the apothecary, and later on was used to relieve the crowded hospitals from outdoor patients as an economic move by the State.

In 1696 Dr. Samuel Garth, an English physician and poet, became a prominent supporter of the new scheme, and his labor in that direction exposed him to the animosity of many of his own profession, especially the apothecaries. That Dr. Samuel Garth appreciated the need of the dispensary for the poor, is evidenced by his poem, a verse of which runs as follows:

THE DISPENSARY.

"There stands a dome majestic to the sight,
And sumptuous arches bear its oval height;
A golden globe placed high with artful skill,
Seems to the distant sight a gilded pill.
This pile was by a pious patron's aim,
Raised for a use as noble as its frame."

That the dispensary is valued highly by the poor is evidenced to-day by the large numbers who avail themselves of its privileges. To ascertain the opinion of the attending staff of the west side Free Dispensary on the question of "Dispensary Abuse," I asked a letter from each physician, and requested an opinion based wholly upon his experience in the dispensary service. I received fifteen letters in reply, some of which, with your indulgence, I will read:

CHICAGO, ILL., Oct. 17, 1895.

Dear Doctor:—Kindly give me at your earliest convenience your idea as to the dispensary abuse (from your own experience in the west side Free Dispensary). That is, to what extent is the medical profession imposed upon by people able to pay for service?

T. A. DAVIS, President.

Dear Doctor:—I must say in reply to the above, that I have kept no record and must depend on my memory and judgment, but I should think about 25 per cent. of the patients are able to pay a reasonable bill for doctor's services, if inclined to do so. It may be that my estimate is a little too high, but it is my opinion that it is not far from right at most.

Fraternally yours,

Dear Doctor:—Replying to your circular favor of Oct. 17, 1895, I would state that in my own limited observation, I have found no case of radical imposition upon the medical profession by those able to pay for medical attendance. Undoubtedly many such people yearly take advantage of our work there, but I believe them to be very much in the minority. Perhaps only a few out of the hundreds of unfortunates.

This has been the result of my own observation.

Fraternally yours,

Dear Doctor:—In reply to your favor of the 17th inst., in which you ask me as to the amount of dispensary abuse in my own clinic at the west side Free Dispensary, is received, and after considerable thought, I have come to the following conclusions:

1. About 15 to 20 per cent. of the patients could possibly pay a reasonable office fee for a few visits, say two to five. They could borrow this amount if necessary to life.
2. A large percentage of the patients have consulted some physician for a few times, and not finding the relief sought, have felt financially unable to continue the treatment and have then sought the dispensary.
3. For prolonged treatment, as for some chronic disease, the percentage able to pay is not over 3 per cent., in my estimation.
4. Almost all of my dispensary cases are chronic in character.

Fraternally yours,

Dear Doctor:—In reply to your request as to what extent I think the medical profession of Chicago is being imposed upon by the treatment of patients in free dispensaries, I will say that in so far as my observation has gone in the west side Free Dispensary, there has not come under my observation any case where I had knowledge or believed the patient was able to pay for services rendered. Of course I have always treated any that came without questioning them as to their financial condition: but in some cases where an operation was needed, and in questioning if they could pay the hospital fee necessary for their board and nurse's attention, 90 per cent. of

them would answer that their circumstances were such at present, that it would be impossible for them to raise the money. Hoping this is satisfactory, I remain fraternally yours.

Dear Doctor: In reply to your inquiry as to the extent of imposition practiced by the public upon the west side Free Dispensary, I have to say that, from my limited experience with the dispensary, I am of the opinion that it is considerable, as at least one-half of my patients or their husbands or fathers were in regular wage-earning employments and consequently not entitled to absolutely free medical services. When the Ringer Bros. circus was here a few weeks ago, four or five of its employees applied for dispensary treatment. I recently had one patient whose husband was employed and earning \$2.75 per diem.

Fraternally yours,

Dear Doctor: In reply to your note of inquiry, I wish to say that, judging from my own experience, the dispensary is a public benefaction. Certainly less than one-fourth of the patients are impostors.

Fraternally yours,

Dear Doctor: In reply to your request of October 17 will say that, while I know personally of many deserving cases, still the undeserving ones are far in the majority. There are very few cases, in my mind, but what are able to pay *something* for services rendered; but how to discriminate between the two remains a puzzle. I candidly believe that the present abuse of the dispensary system should be corrected in some way, if a possible thing to do so. I am fraternally yours.

I have marked the percentage of impostors as I judged to be fair from the expression given in each letter, and I find the average to be about 20. That would leave 80 per cent. of those receiving attention as in need of charitable aid, and at this rate our dispensary alone has been a benefactor to two hundred and eight thousand people during the past decade. This is conclusive evidence as to the value of the dispensary to the sick poor, though I do not know that the poor could not be as well served with less sacrifice to the profession and with lessened tendency to pauperization of the poor.

That the dispensaries are maintained chiefly from philanthropic motives appears untrue. At this time the dispensary is considered an indispensable factor in a medical college, and in addition to the duties devolved from a philanthropic standpoint college requirements have entered largely into dispensary management, so that now the prime object of dispensary maintenance is educational.

The first in importance of these demands made by the college on the dispensary is in the way of material for college clinics. The second is for the proper clinical instruction to be given by the dispensary teachers, and the last we may say is beneficent, for the care of the sick poor.

In the past the dispensary has been the main source of supply for material for the clinical instruction of students in our principal medical colleges, and the service has been considered as of much value. It has been of some value, but I venture to say that if Cook County Hospital would open its doors to the medical student for the bedside study of disease (with proper restrictions under the supervision of the medical staff) the college dispensaries could be done away with, with profit to the former institution and to the medical profession and humanity at large. This at first might seem audacious, but when we investigate more closely the character of the instruction given in college clinics, it will be readily seen that the important detail of scientific clinical study is never known. The patient appearing for the first time in his life before a large class of medical students, is ushered in without his history being known, and in most instances, I venture to say that when he has taken his departure from the clinic there is little doubt but he has proved an "alibi." But the clini-

cian is guilty before the eyes of science for so disposing of his material without exhausting the various means for making a diagnosis. His therapeutics is worse than useless, for the pathology of the case has gone unrecognized. These clinics (I have no reference to college clinics supplied from hospital material) are given upon ambulatory patients, and time is not given to the essential branches of the science, diagnosis, pathology and therapeutics. So that I almost question their utility as educational means at all. It is in the hospital alone that these most important branches can be studied.

Reasoning, then, that just in the degree that these imperfections occur in the use of patients in scientific clinical teaching does the value to the sick poor depreciate, I conclude that a change from the present dispensary system is most desirable. Before suggesting a remedy which I think will appear in harmony with scientific charity organizations, I wish to allude to the character of the men who have served as physicians in our principal dispensaries, and if my statements can not be truthfully controverted, it is the dispensary system and not the men which is at fault.

In this city, from the father of the greatest medical association in this country, down to the promising young member of the profession, nearly all have served their time in the dispensary.

The men who have accomplished most in advancing the interests of the profession scientifically, have written our medical books, and have been the educators of our present medical profession in colleges, have nearly all served their time in the dispensary. This fact, *per se*, is all that could be desired as evidence of the high moral and intellectual tone of the institution. Credit should be given to an institution so noble in its aim. It has served its purpose until now; modern scientific charity demands a cessation of the indiscriminate free offerings on account of its demoralizing and pauperizing influence upon the poor.

It has served a good purpose in stimulating the minds of dispensary teachers to study and to teach; and many diseases have been justly dealt with in exemplification of the subject at hand; but the crowding into an hour's time of so many ambulatory cases means necessarily such hasty dealing with the patients that the present dispensary system is certainly unsatisfactory, and we should hail with delight a system which would meet all the requirements of the times. May I suggest the following as a remedy:

That the County Hospital be opened to the medical student for the bedside study of the sick.

That the physicians attending that institution be selected for their ability to teach medicine, and that they be put under civil service rule.

That the present method of caring for the "at home sick" be continued by the county, through the county agent, who can investigate each case to prevent the imposition from those who are able to pay for services.

That the ambulatory sick poor, through an order from the county agent, shall be treated at a department arranged for that purpose at the County Hospital.

This, it seems to us, would provide well for the needy poor and prevent imposition, and at the same time give ample facilities for proper clinical teaching. Then there could be no excuse for the existence of those dispensaries which are maintained solely for the prestige given to the physicians who attend them

(and twenty-one of the thirty dispensaries existing in this city to-day are of that class). Now then, by resolutions being passed and distributed by the medical societies of this city, deprecating them, the "dispensary evils" would soon be abolished, and thus the profession protected from the imposition now existing so extensively.

In our scheme we have contemplated the arrangement of three classes of cases:

1. The hospital cases.
2. "At home" cases which are now being cared for by the dispensary, which has received the small appropriation from the county (\$1,500 yearly for about 10,000 sick calls), barely enough to purchase the necessary medicines, and which apply through the county agent for medical attention. To reach this class of cases, the dispensary having charge of the west side of the city has divided it into nine districts—each district attended by one physician who is paid simply car fare from the dispensary.

3. Ambulatory patients who now rove around from dispensary to dispensary.

We would establish a bureau of clinical instruction with headquarters at the County Hospital. The function of this office should be to classify the clinical courses to be given, and to arrange the medical students into classes for methodic work. Small bedside classes, medical, surgical, gynecologic, dermatologic, obstetric, etc. Large classes in amphitheater, small classes in ambulatory patient department, and small classes for outside visiting departments. As to the ambulatory patients' department, or the dispensary department proper, I would adopt means of inquiry, with the object of excluding those who are not in need of charitable aid (and great care and kindness must be exercised in this department so as not to increase the mental suffering of those who are driven to accept charitable assistance). Complete histories are to be written in all cases and kept on file in the department to which the patient is assigned, and a record made on this history sheet of each visit made together with the treatment given.

Chicago has sent out to the world, chiefly to the great Northwest country, some 30,000 doctors to whom she never gave an opportunity to learn practical medicine by bedside study. Think of this great cosmopolitan city with her charity hospital, drawing its patients from two millions of people, and wonder why she does not reciprocate to the country which has so generously supplied her with the blood of commerce, by providing the country with the amplest opportunities possible for the education of its physicians. This she can do by opening the doors of her great institution for efficient clinical instruction.

AN AURAL MASSEUR.

BY EDWARD J. BROWN, M.D.

MINNEAPOLIS, MINN.

At the present time an aural masseur which is practical, safe and not too expensive, would seem to be a much felt want.

As a very simple and reasonably effective instrument I can commend the Ziegler otoscope with stiff rubber bag attachment, which I purchased in Heidelberg six years ago. With a soft rubber tube for fitting the otoscope tightly in the external canal, any safe and desirable amount of exhaustion or pressure

may be secured. No competent aurist would ever think of applying such a force to the drum membrane without being able to note the effect. Having the instrument in position I have been in the habit of drumming upon the bag with the four fingers of the right hand, having found that by this means I could make from 500 to 600 distinct impressions upon the membrana tympani in a minute. The stiff bag is not a necessity, as I have found that an ordinary syringe bulb answers a very good purpose. With this instrument I have relieved a long-standing case of tinnitus aurium by six treatments.

A far easier instrument to use and so a more effective one, I have lately constructed with the aid of my friend and jeweler, Mr. Carl T. Thayer. This is a machine involving the piston action of the Chevalier Jackson masseur. It is made up of an inexpensive jeweler's lathe and a small pump attached to the table of a sewing machine. The eccentric is so great that the extension of the piston may be varied from zero to two inches, and the machine is so geared that with foot power alone from 2,000 to 3,000 movements of the piston may be easily made.

My object in this publication is not to exploit anything particularly original, but to make it possible for any aurist who desires a masseur that is neither "cheap and nasty" nor dangerous, to secure one without "mortgaging his farm."

THE NECESSITY FOR CONSTRUCTING ANOTHER HOSPITAL FOR THE INSANE IN ILLINOIS.

BY BOERNE BETTMAN, M.D.

PROFESSOR OF OPHTHALMOLOGY AND CLINICAL OTOTOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS; PROFESSOR OF OPHTHALMOLOGY IN THE POST-GRADUATE MEDICAL SCHOOL; PRESIDENT OF THE ILLINOIS STATE BOARD OF CHARITIES.

CHICAGO.

The need of another insane hospital must be evident to any one who has beheld the poor accommodations accorded to the insane detained in the county poorhouses. The best authorities the world over are unanimous in their opinion regarding the necessity of State care for these defective individuals. The four institutions which now exist accommodate 5,000 patients, fully 2,000 more are scattered throughout the State and should, in our judgment, find lodgment in State buildings thoroughly equipped for their care and treatment. For further particulars regarding the construction of building and the most advanced methods for the care and treatment of the patients and other matters relating to the subject of insanity, we refer to the excellent reports prepared at the suggestion of Governor Altgeld by the superintendent and medical staff of the State lunatic asylums. They have appeared in print under the heading, "Compilation of Special Reports of Superintendents of Illinois State Institutions."

Another institution with a capacity of 1,000 beds for the care of both chronic and acute cases requires the immediate attention of the Legislature. In order to obtain an adequate expression of opinion of salient features which are involved in the erection of such an edifice, the following letter was sent to authorities in this and foreign countries:

"The State of Illinois has about 7,000 insane in public and charitable institutions. Five thousand are cared for in State hospitals, the remaining 2,000 are in hospitals and wards of the poorhouses of the counties.

ANSWERS TO THE CIRCULARS OF THE STATE BOARD OF CHARITIES WITH

ANSWER FROM.	STATE CARE FOR ALL THE INSANE.	SPECIAL HOSPITAL FOR INCURABLES.	WHAT PERCENTAGE OF PATIENTS CAN WORK ON THE FARM.
Dr. Liebe, Bielefeld (German epileptic colony). F. Kölle, Zurich. (Epileptische Anstalt).	State care preferable under all conditions.	Not desirable, because it deprives the other hospitals of a working force (farm, shops, etc.) Two such institutions exist in the Canton of Zurich, besides one for acute cases.	Depends on the population and the prevalent forms of disease.
J. Morel, Ghent. (Highest authority.)	State care preferable if frequent inspections by competent inspectors are made, to stimulate the care of the patients and the work of the medical staff.	Opposed to the principle. Draws attention to the fact that a very great number of idiots and imbeciles can be taught a trade for help in asylums. Special institutions for idiots can suffice to provide the other institutions with clothes and food. Extension of workshops. Special hospitals for the chronic and insane epileptics recommended (compare his pamphlet).	Up to two-thirds.
Dr. Zinn, senior, Eberswalde near Berlin.	State care preferred.	Board opposed to incurable hospitals.	Between 40 and 60 per cent.
J. P. Byers, State Board of Charities, Ohio.	State care.	Less expensive hospital may be built for incurables.	From 50 to 60 per cent. employed at "something."
Henry M. Hurd, Supt. of Johns Hopkins.	State care essential. Refers to New York experience.	Less extensive buildings for incurables, but on the same plant.	10 to 15 per cent. male patients can work on the farm. 20 per cent. female patients can be employed in gardens, laundries, etc. 30 per cent. of male patients (estimate) could work on farm.
Dr. Wise, St. Lawrence Hospital, New York.	State care.	Might be cheaper.	57.6 per cent. employed, 292 patients live on a farm 3 miles from hospital.
Dr. Edwards, Kalamazoo. Dr. Edward F. Wells, Chicago.	State care essential. Cites experience in Illinois.	Not desirable. Cites experiences of New York, Massachusetts and Pennsylvania. If buildings for the insane are very cheap they are not safe, and if entirely safe they are not very cheap. Every advantage of economical provision and maintenance of comfort and occupation, which the chronic insane may have in separate asylums, may be afforded them in hospitals for all classes; and further, if any division of this kind will cost less for the chronic, it will add correspondingly to the cost for the care of the acute cases.	About 50 per cent. of the males. An equal population of the females may be employed in other directions. Useful employment is pleasurable and remedial—enforced idleness is a grievous punishment.
Dr. Hertinz, Alt-Scherbitz.	State care by all means. More economical and humane.	Acute and chronic cases to be cared for in the same institution but the chronic in separate, cheaper buildings with less expensive care.	70 to 80 per cent. occupied in colony.
Dr. G. W. Jacoby, New York.	State care only.	Cheaper but substantial hospitals for incurables. (New Pennsylvania hospital for the chronic insane.)	About 20 to 25 per cent. of male patients. 18 to 20 per cent. of female patients.

"Governor Altgeld decided in 1892 that the existing State hospitals should not be enlarged, but that a new hospital should be built. In order to avail ourselves of the most advanced thought and of recent experience, we beg to address to you the following circular containing a number of questions to which you will be kind enough to give us an answer from your personal experience:

"Would you prefer care of the incurable in county hospitals and poorhouses at the expense of the counties, to care at the expense of the State, either with mere State supervision or with concentration of those patients in State hospitals?

"Does the difference in the needs between curable and incurable patients justify the construction of a less expensive hospital for the chronic incurable?

"What percentage of patients do you judge fit for work on a farm (after the plan of Alt-Scherbitz in Germany)? First, male; second, female.

"Is a separate institution for epileptics desirable, and to what extent will it relieve the insane hospitals?

"Is the Scotch boarding-out system feasible in this country?
"What is, to your knowledge, the best plan for hospital of a thousand patients?

"1. For largely acute cases. (What percentage of those cases would require special medical care and nursing in real hospital wards and watch-wards, after the arrangement of Dr. Scholtz, in Bremen, compare *Allg. Zeitschr. f. Psychiatrie*, Vol. 50?)

"2. Hospital for chronic patients."

The answers to the above were pregnant with good advice and the results of years of experience. We submit a number of them in a condensed form. (See table.)

It will be observed that the prevailing thought is to improve the surroundings of the insane by placing them under State control. To construct the buildings after the pattern of Alt-Scherbitz which tends to

REFERENCE TO THE CONSTRUCTION OF A NEW INSANE HOSPITAL.

DESIRABILITY OF A SEPARATE INSTITUTION FOR EPILEPTICS.	BOARDING-OUT SYSTEM.	BEST PLAN FOR A HOSPITAL; STYLE OF HOSPITAL FOR THE ACUTE CASES.	REMARKS.
Desirable.		Alt-Scherbitz. All acute cases should have supervision and care of physicians.	
<p>Colony.</p> <p>Gives very good plan for an epidemic colony:</p> <ol style="list-style-type: none"> 1. House for children with school. 2. Houses for patients able to work. <ol style="list-style-type: none"> a. Male. b. Female. <p>Occupation in gardens, agriculture, book binding, carpenters, tailors, basket makers, carpet weavers, cobblers, etc. Trades with fire or building excluded.</p> <ol style="list-style-type: none"> 3. Houses for insane epidemics. 4. Infirmary. 5. Farm, buildings. <p>Morel is not too enthusiastic on this point. Difficulty in distinguishing epileptic insanity from insanity in patients with epileptic fits. Does not seem quite conclusive.</p>			A book in the press on epileptic colonies by Dr. Kölle.
Favors special wards for epileptics.	Not favorable in America. Rather unite those patients and employ them like the idiots and feeble-minded in workshops, etc.	Refers to his pamphlets preparing the construction of two large asylums (1,000 patients each) built according to his plans.	Letter very important written in English.
The institution for epileptics founded 1893, at Gallipolis, will ultimately receive all the epileptic insane.	Proved a fair success in Massachusetts because there are enough impoverished families of good breeding.	No congregate buildings recommended.	Pamphlets sent.
Separate institutions for epileptics desirable as a relief to insane hospitals.	Pavilion plan.	Central hospital with 100 beds for each sex for acute and hyper-acute cases. Remaining 800 cases in three groups of buildings. Infirmary one-story buildings; remaining two for industrial patients of each class.	Refers to his reports.
It will relieve the hospital from an undesirable population having a bad effect upon the system.	Not a success in this country.		
Desirable. Would relieve asylums of Michigan of 7½ per cent.	Not a success here.		
Insane epileptics should be retained in insane hospitals. An institution—largely industrial in character—is needed for non-insane epileptics who are public charges. They require an especial care which cannot be given them in almshouses.	Neither desirable or successful in this country.	Buildings in four groups, viz.: Hospital group, for both sexes, to accommodate 20 percent. of inmates; group for convalescent and mild cases, for both sexes (in widely separated buildings) with a capacity for 20 percent. of inmates; a general wards group for males, and a general wards group for females, each with capacity for 30 percent. of inmates. The wards should not be too large and should be arranged to facilitate efficient supervision. They should be on one floor—each complete in itself—and in two story, fireproof, or semi-fireproof, pavilions. The cost should be moderate—neither cheap nor expensive—and certainly not extravagant.	Refers to papers on "Hospitals for the Insane—their Scope and Design," which was submitted to the board.
Special colony for epileptics rather desirable.	Boarding-out system questionable.	Cottages containing 30 to 40 patients. In chronic cases 70 to 80 may be housed in one building.	Refers to Die Kolonisierung der Geisteskranken in Verbindung mit dem Offen-Thur-System, ihre historische Entwicklung und die Art ihrer Ausführung auf Rittergut Alt-Scherbitz, von Dr. Albrecht Paetz.
Special institutions for epileptics to avoid deleterious influences of one class of patients upon the other.	Decidedly impracticable in this country.	<p>(a) For largely acute cases, the "block" system with special observation and hospital wards best represented by the plan of one of the Riding asylums in England, and New Bloomingdale Asylum at White Plains, New York.</p> <p>(b) Hospital for chronic insane, cottage system as it exists in Alt-Scherbitz.</p>	

overcome the penitentiary appearance and impressions so painfully pronounced in most of our institutions. To replace in most instances methods of restraint by the substitution of means of employment and outdoor pursuits which are prone to stimulate into healthy activity all of the functions of the body. Another noteworthy feature which of late years has come into prominence as a means of rendering more efficient the attempts at restoring the perturbed mind to its normal condition, is the establishment of a nurses' training school. The cure of insanity depends largely on influences exerted over the mind. The employment of drugs plays but a small factor in reaching the desired end. Everything depends upon psychic effects which must in a large measure be called forth by the individuals under whose constant

supervision the patients are placed. It will therefore be apparent that these attendants must be well instructed to perform their duties. The diverse nature of insanity demands a variety of methods, depending upon the individuality of the patient.

A great evil which exists in large institutions is the stereotyped and uniform regimen to which the mentally diseased are subjected. This is largely due to the insufficient number of attendants and to their lack of preliminary training. The system now in vogue in general hospitals, namely, that of educating a competent corps of nurses, should be introduced into hospitals for the insane. It would redound to the credit of the State, and by restoring to reason a larger percentage of the insane, probably would prove an economical measure.

SELECTIONS.

Effect of Removal of Supra-Renal Capsules.—Brinet records some new experiments with his eleven rats whose supra-renal capsules he removed a long while ago. He finds that they can bear fatigue from muscular exertion and artificial irritation just as well as normal rats. Two of his rats were killed and dissected and the capsules had not started to grow again.

Other writers assert that accessory capsules are not unusual in rats, and this perhaps explains why eleven of the rats lived out of the seventy-five he operated upon, and why they can bear fatigue. *Centralblatt für Physiologie*.

Experimental Study of Pancreatic Diabetes. Chabad has removed the pancreas in animals, and in each case it has produced acute diabetes mellitus. Partial removal only produces symptoms similar to those of diabetes insipidus. The removal of a larger portion causes slight diabetes mellitus, and of the entire pancreas the acute form. He concludes that the pancreatic diabetes thus produced is entirely due to the removal of the pancreas and not to any functional disturbance in other organs. The blood loses its alkalinity in this diabetes, and as the pancreas supplies alkali to the blood, with its removal the blood ceases to be alkaline. The favorable effect of alkalies in diabetes can thus be explained by these experiments on animals. They have fully established the fact of the existence of pancreatic diabetes. — *Gazz. degli Osp. e Clin.*

Serotherapy in the Treatment of Cancer.—A number of French observers have been experimenting with this treatment, and although they have not succeeded in effecting a complete cure, yet what they have accomplished is remarkable. 1. In the fifty cases they studied, the pain subsided immediately, and this unexpected phenomenon lasted during the entire course of treatment. 2. The ulcerations improved, healthy granulations and scabs formed, while the tendency to bleeding diminished. 3. The swellings grew smaller, the infiltration of the neighborhood ceased, the infiltrated glands shrunk, and the entire cancer often showed considerable decrease in size. 4. In the severest, most hopeless cases, the development of the cancer seemed definitely arrested. 5. The general health improved.

Three months of this improvement were followed by a stationary stage. After a while new knobs were found near the almost healed center, but their development was very slow. The injections produced slight exanthema in a few cases. They were followed by syncope in four, but all phenomena tend to prove that the course of the cancer was very much delayed by this treatment. *Centralblatt für Chirurgie*, Jan. 11, 1896.

The Bacteria of Catgut and Its Sterilization. Dr. Lajackowski writes to the *Przeglad Chir.* that he finds another bacillus in catgut beside Brunner's, which he calls alpha catgut bacillus, while he names his beta. The beta bacillus is a thin long rod with rounded ends, extremely movable. Certain differences between the alpha and beta appear when line and drop cultures are made of them, which must be referred to the originals to be studied. Both showed powerful resistance to the action of antiseptics and also to dry and moist heat, in both of which the beta surpassed the alpha. His experiments in this line were very interesting, as also his efforts to ascertain the effect produced by these bacilli on the living organism, especially where they prepared a soil for the pus cocci. His experiments resulted in finding that while subcutaneous and intravenous injections of both alpha and beta in rats produced no perceptible effect, yet, when mixed with streptococci, they caused the death of the animal in two to three days with general septic symptoms. He concludes, therefore, that the catgut bacilli are harmless in themselves, but seem to increase the injurious effects of the pus cocci. He announces that catgut can be thoroughly sterilized by soaking it twenty-four hours in ol. juniperi twelve

hours in ether and sixty hours in hydrochloric acid (1 to 500). Another method is to apply the Reverdin-Braatz process, temperature 150°. Still another is to keep it in boiling xylol two and one-half hours. *Centralblatt für Chir.*, Jan. 4, 1896.

Pathology of Castration for Hypertrophy of the Prostate Gland.—This is now one of the questions of the day, and the fact has been established that castration produces the desired atrophy. Prjewalsky has been experimenting in Russia to find out the cause for this result of castration. He has removed the testes of dogs, the nerves of the seminal plexus in some, and experimented in various ways. He finds that the nerves play the principal part in this problem, which is very complex. His conclusion is that it is the lack of anatomic continuity in certain nerve fibers which produces the atrophy after castration. In every case where he removed the external seminal nerves in a dog, there was disordered testicular secretion at once. Suppressing the function of the internal seminal plexus produced complete testicular atrophy, resulting in the entire disappearance of the parenchyma of the organ. The excision of "Cooper's nerve" produced atrophy of the prostate gland, but had no effect whatever upon the size of the testes. — *Gaz. Méd. de Paris*, Jan. 11, 1896.

Estimation of Blood-Corpuscles. The *Centralblatt für Physiologie* states that Bleibtren's method of determining the volume of the corpuscular elements in the blood has been criticised unfavorably by Eykman (*Pflüger's Arch.*, 50, p. 340), who points out the following most important error: According to the formula to be used in the calculation the volume of the blood-corpuscles is altogether too small, notwithstanding the fact that they are increased in size, whenever the blood is diluted with a hypotonic solution. This is owing to the decrease in the amount of water in the serum. After a detailed account of the operation of this and other sources of error, he describes certain experiments which show that the 0.6 per cent. solution of common salt advocated by Bleibtren, produces marked deviations from the correct estimates obtained when isotonic solutions are employed. After noting the lowering of the freezing point, he measured the osmotic energy of the serum according to Gryns' method. This is based on the assumption that the volume of the blood-corpuscles remains unchanged in a liquid which does not affect their substance, if the liquid has the same osmotic energy as the original serum. It proceeds by centrifugizing defibrinated blood to the constant volume of the residuum. The liquid above is then removed and replaced in several different simultaneous tests by solutions of salt, varying in strength, and centrifugized until the balance is restored. A solution which does not produce any change in the residuum he considers isotonic.

Bleibtren's objections to this centrifugal method only apply when the diluting liquid affects the substance of the corpuscles. Harmonious estimates of the blood unmixed, or mixed with solutions of salt approximately isotonic, are certainly obtained by this method. It also establishes the fact that the substance of the blood-corpuscles increases considerably when mixed with a 0.6 per cent. solution of salt.
